Abstract

Electrochemical impedance spectroscopy (EIS) is one of the most important techniques in electrochemistry. However, analyzing the EIS data is not a simple task. The distribution of relaxation times (DRT) method offers an elegant solution to this considerable challenge. In addition to that, the DRT method can be used to obtain the time characteristics of the electrochemical system under study. Though, deconvolving the DRT from the EIS data is an ill-posed problem, which is particularly sensitive to experimental errors. Several well-known approaches, including ridge regularization, can overcome this issue but they all require the use of *ad hoc* hyperparameters. Furthermore, most methods are not probabilistic and therefore do not provide any uncertainty on the estimated DRT. In this work, by assuming that the DRT is a Gaussian process (GP), it is not only possible to obtain the DRT mean and covariance from the EIS data but also to predict both the DRT and the imaginary part of the impedance at frequencies not previously measured. One important point to note is that, unlike other methods, the parameters that define the GP-DRT model can be selected rationally by maximizing the experimental evidence. The GP-DRT approach is tested using synthetic experiments for analyzing the consistency of the method and “real” experiments to gauge its performance for real data. The GP-DRT model is shown to be able to manage considerable noise, overlapping timescales, truncated data, and inductive features. Considering the GP-DRT framework developed and the results of the simulations, the GP-DRT will likely inspire further studies on using a probabilistic approach to interpret EIS data.

1. Introduction

Electrochemical impedance spectroscopy (EIS) is one of the most commonly used characterization techniques in the field of electrochemistry [1, 2, 3, 4, 5, 6, 7]. EIS experiments have been used to understand the physicochemical processes taking place in numerous electrochemical systems (ECSs), including fuel cells [8, 9, 10, 11, 12, 13, 14], batteries [15, 16, 17, 18, 19, 20, 21], solar cells [22, 23], and supercapacitors [24]. EIS has also been used in other fields including biology [25, 26, 27] and medicine [28, 29]. The EIS spectrum is particularly useful because it contains time-dependent information and covers a broad span of timescales, allowing the recovery of many physical properties, such as diffusion coefficients and reaction rate constants [4, 30]. During an EIS measurement, the ECS is subjected to a small sinusoidal perturbation in current/bias, and concomitantly the resulting bias/current is recorded [2, 5, 7]. At a given frequency, the impedance is obtained from the ratio and the dephasing of the bias/current. To obtain the full EIS spectrum, this procedure is repeated over a broad range of frequencies, usually, from mHz to MHz.

Despite the EIS technique being highly effective, interpreting the EIS data can be challenging [31]. To that end, equivalent circuit models (ECMs) [2, 5] are often used. However, ECMs have significant limitations. First, they are often chosen in an *ad hoc* fashion and often are just circuit analogs [32]. Second, they are not unique. It is not uncommon to encounter situations where multiple plausible ECMs can fit the EIS data equally well [33]. Compared to selecting *ad hoc* ECMs, physical models are far more informative of the actual electrochemical processes taking place in the ECS under study [6, 22, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44]. However, physical models are not used as often as ECMs because, as they are system-specific, they require considerable implementation work.

To overcome the challenges mentioned above, the distribution of relaxation times (DRT) has recently attracted significant research attention [45, 46, 47, 48, 49, 50]. The idea behind the DRT is to deconvolve the EIS spectrum into a distribution of timescales. This is useful because the time scales can be used to guide the design of ECMs [45] or to identify different physical processes [10, 51, 52, 53, 54, 55, 56]. The DRT model assumes that the voltage response of an ECS to a step current perturbation decays exponentially with a particular distribution of timescales [46, 48].

It can be shown that, if this hypothesis holds, then the impedance can be written as

$$Z^{\text{DRT}}(f) = i2\pi f L_0 + R_\infty + \int_{-\infty}^{\infty} \frac{\gamma(\log \tau)}{1 + i2\pi f \tau} d \log \tau \quad (1)$$

where L_0 is an inductance, R_∞ is a resistance, f is the frequency, and $\gamma(\log \tau)$ is the DRT, which is a function that determines the timescale distribution [10].

Deconvolving the DRT from the EIS data is not simple because one needs to solve an inverse problem, which is ill-posed [45, 49, 57]. That is, its solution is particularly sensitive to experimental errors. A variety of numerical frameworks have been developed to resolve ill-posedness and have leveraged methods as diverse as Fourier transform [50], maximum entropy [58], fractional algebraic identification [59], Monte Carlo sampling [60], genetic

algorithms [61, 62, 63], ridge regression (RR) [47, 48, 49, 57, 64], and elastic-net regularization [65]. One case of particular interest is ridge regression because the DRT deconvolution can be recast as a constrained quadratic programming problem, which solves

$$\arg \min_{\mathbf{x} \geq 0} \left\{ \sum_{n=1}^N \left[w'_n (Z_{\text{re}}^{\text{exp}}(f_n) - Z_{\text{re}}^{\text{DRT}}(\mathbf{x}, f_n))^2 + w''_n (Z_{\text{im}}^{\text{exp}}(f_n) - Z_{\text{im}}^{\text{DRT}}(\mathbf{x}, f_n))^2 \right] \right\} + \lambda \|\mathbf{L}\mathbf{x}\|^2 \quad (2)$$

where w'_n and w''_n are suitable weights, $Z_{\text{re}}^{\text{exp}}$ and $Z_{\text{im}}^{\text{exp}}$ are the real and imaginary part of the experimental impedance, respectively, f_n is the n th frequency, \mathbf{x} is an unknown vector that represents the DRT, and $\lambda \|\mathbf{L}\mathbf{x}\|^2$ is a regularizing term weighted by the hyperparameter λ where \mathbf{L} is a suitable differentiation matrix. While the RR can be recast in Bayesian context to recover the DRT and its uncertainty, the choice of the hyperparameter(s) is arbitrary and the only available method is cross-validation [57]. Furthermore, the DRT model has been only used to fit the experimental EIS data and has yet to be used to predict the EIS at frequencies other than the ones measured. This may prove useful in situations where experimental limitations may prevent measurements at certain frequencies (e.g. low frequencies because of time limitations or high frequencies because of instrument limitations) [66].

To overcome the difficulties inherent to selecting hyperparameters and predicting EIS values at unmeasured frequencies, we develop the GP-DRT method. This new method leverages Bayesian statistics and, specifically, Gaussian processes (GPs). Instead of deconvolving the DRT to obtain a simple curve using (2), we interpret the DRT as a GP. It is important to note that GPs in the context of machine learning provides a non-parametric approach for inferring functions from data. Therefore, a GP can be viewed as a Bayesian prior over a functional space [67, 68]. First, we assume that the DRT, $\gamma(\log \tau)$, is an unseen (or latent) GP. Second, we note that $\gamma(\log \tau)$ gives the impedance following (1). Using the property that GPs are closed under linear transformations [67, 69], the obtained $Z^{\text{DRT}}(f)$ is also a GP. Leveraging the last two properties, we will conduct regression and prediction.

In the following sections, we will first define what GPs are. Using GP regression, we will recover and predict the DRT and the impedance. For all practical purposes, we will use multivariate Gaussian random variables (RVs) to correlate $\gamma(\log \tau)$, $Z^{\text{DRT}}(f)$, and the experimental data. An extremely important point to note is that the hyperparameters do not need to be guessed. Instead, these parameters are obtained by maximizing the experimental evidence, that is, the probability that the experimental result is obtained under the assumptions of the GP model. Furthermore, synthetic experiments as well as “real” experiments show that the GP-DRT model can recover both the DRT and the imaginary part of the impedance well. Lastly, we point out the strengths and weaknesses of the GP-DRT approach and propose future research directions.

2. Theory

2.1. Gaussian Processes

2.1.1. Basics

A Gaussian process (GP) can be loosely defined as an infinite collection of RVs, such that every finite subset of these variables follows a multivariate normal distribution [67, 68]. Here, we focus on regression and prediction, as is typical of machine learning and assume that the function we wish to learn is a GP. Both GP regression and prediction are Bayesian methods [70]. One should note that such methods are not the same as the frequentist approaches more commonly used in the electrochemical field [2, 4, 7, 32], where one simply fits a model such as an equivalent circuit or a physical model, to the experimental data to obtain an estimate of a parameter. In fact, being Bayesian, the GP-DRT provides the probability distribution function of $\gamma(\log \tau)$ given the experimental observations.

Let us be more formal and consider $g(\mathbf{x})$ as a GP with a mean function $m(\mathbf{x})$ and a covariance (or kernel) function $k(\mathbf{x}, \mathbf{x}')$, *i.e.*,

$$g(\mathbf{x}) \sim \mathcal{GP}(m(\mathbf{x}), k(\mathbf{x}, \mathbf{x}')) \quad (3)$$

where \mathbf{x} and \mathbf{x}' both are input points. We remark that $m(\mathbf{x}) = \mathbb{E}[g(\mathbf{x})]$ and that $k(\mathbf{x}, \mathbf{x}') = \mathbb{E}[(g(\mathbf{x}) - m(\mathbf{x}))(g(\mathbf{x}') - m(\mathbf{x}'))^\top]$, where $\mathbb{E}[\cdot]$ is the expectation. If we initially assume $m(\mathbf{x}) = 0$ [68, 67, 70] and take N experimental observations at $\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N$, then (3) defines a joint Gaussian distribution $p(g(\mathbf{x}_1), \dots, g(\mathbf{x}_N))$ given by

$$p(g(\mathbf{x}_1), \dots, g(\mathbf{x}_N)) = \mathcal{N}(\mathbf{0}, \mathbf{K}) \quad (4)$$

where $\mathcal{N}(\mathbf{0}, \mathbf{K})$ is the Gaussian or normal probability distribution function with zeros mean and covariance \mathbf{K} . \mathbf{K} is defined as $(\mathbf{K})_{ij} = k(\mathbf{x}_i, \mathbf{x}_j)$ with $i, j = 1, 2, \dots, N$ or as a shorthand $\mathbf{K} = k(\mathbf{X}, \mathbf{X})$ with $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_N)$.

For a given measured dataset $\mathcal{D} = \{(\mathbf{x}_n, y_n), n = 1, 2, \dots, N\}$, where the observation y_n is the realization of $g(\mathbf{x}_n)$, we can calculate the posterior, *i.e.*, the probability of g known the data $\mathbf{y} = (y_1, \dots, y_N)^\top$. More specifically, it can be supposed that the observed dataset \mathcal{D} has noise $\varepsilon \sim \mathcal{N}(0, \sigma_n^2)$, such that $y_n = g(\mathbf{x}_n) + \varepsilon$. Our goal is to predict $g(\mathbf{x}_*)$, the value of the GP $g(\mathbf{x})$ at an unobserved point \mathbf{x}_* . Following the definition of GP, \mathbf{y} and $g(\mathbf{x}_*)$ are correlated and have a joint multivariate Gaussian distribution:

$$\begin{pmatrix} \mathbf{y} \\ g(\mathbf{x}_*) \end{pmatrix} \sim \mathcal{N} \left(\mathbf{0}, \begin{pmatrix} \mathbf{K} + \sigma_n^2 \mathbf{I} & \mathbf{k}_* \\ \mathbf{k}_*^\top & k_{**} \end{pmatrix} \right) \quad (5)$$

where $(\mathbf{k}_*)_n = k(\mathbf{x}_*, \mathbf{x}_n)$ or $\mathbf{k}_* = k(\mathbf{x}_*, \mathbf{X})$, $k_{**} = k(\mathbf{x}_*, \mathbf{x}_*)$, and \mathbf{I} is the identity matrix. As \mathbf{y} is known from the dataset \mathcal{D} , the probability distribution function of $g(\mathbf{x}_*)$ conditioned on \mathbf{y} has the following expression [68], see

Appendix A:

$$p(g(\mathbf{x}_*)|\mathbf{x}_*, \mathbf{X}, \mathbf{y}) = \mathcal{N}(\mu_{\mathbf{x}_*}, \Sigma_{\mathbf{x}_*}) \quad (6)$$

with

$$\mu_{\mathbf{x}_*} = \mathbf{k}_*^\top (\mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{y} \quad (7a)$$

$$\Sigma_{\mathbf{x}_*} = k_{**} - \mathbf{k}_*^\top (\mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{k}_* \quad (7b)$$

85 Therefore, this procedure allows the prediction of $g(\mathbf{x}_*)$ as a normal RV with mean $\mu_{\mathbf{x}_*}$ and covariance $\Sigma_{\mathbf{x}_*}$.

2.1.2. Linear Transformations of Gaussian Processes

One useful property that will be exploited is that GPs are closed under linear transformations [67, 69]. This implies that, if a linear functional¹ $\mathcal{L}_{\mathbf{x}}(\cdot)$ is applied to $g(\mathbf{x})$, then $\mathcal{L}_{\mathbf{x}}(g(\mathbf{x}))$ is also a GP. In particular, if $g(\mathbf{x})$ is defined as in (3), then

$$\mathcal{L}_{\mathbf{x}}(g(\mathbf{x})) \sim \mathcal{GP}(\mathbf{0}, \mathcal{L}_{\mathbf{x}}(\mathcal{L}_{\mathbf{x}'}(k(\mathbf{x}, \mathbf{x}')))) \quad (8)$$

90 and

$$\begin{pmatrix} g(\mathbf{x}) \\ \mathcal{L}_{\mathbf{x}}(g(\mathbf{x})) \end{pmatrix} \sim \mathcal{GP}\left(\mathbf{0}, \begin{pmatrix} k(\mathbf{x}, \mathbf{x}') & \mathcal{L}_{\mathbf{x}'}(k(\mathbf{x}, \mathbf{x}')) \\ \mathcal{L}_{\mathbf{x}}(k(\mathbf{x}, \mathbf{x}')) & \mathcal{L}_{\mathbf{x}}(\mathcal{L}_{\mathbf{x}'}(k(\mathbf{x}, \mathbf{x}')) \end{pmatrix}\right) \quad (9)$$

2.2. The DRT Formulation

Here the DRT model given in equation (1) is reformulated so as to exploit the properties illustrated in Section 2.1.2. It should again be noted that the DRT framework rests upon the assumption that we can model the impedance $Z^{\text{DRT}}(f)$ as [48, 46]

$$Z^{\text{DRT}}(f) = i2\pi f L_0 + R_\infty + \int_0^\infty \frac{1}{1 + i2\pi f \tau} g(\tau) d\tau \quad (10)$$

95 where $g(\tau)$ is a timescale distribution [10] and $\gamma(\log \tau) = \tau g(\tau)$.²

The EIS is usually measured with the frequencies spanning across several orders of magnitude, typically from mHz to MHz. Therefore, it is natural to define the log-frequency $\xi = \log f = -\log \tau$, so that (1) can be rewritten

¹A functional is a function that has as input a function and as output a number.

²We note that we use the $\log(\cdot)$ improperly and we should understand that both f and τ are dimensionless variables.

as

$$Z_{\text{re}}^{\text{DRT}}(\xi) = R_{\infty} + \int_{-\infty}^{\infty} \frac{1}{1 + \left(2\pi e^{\xi - \hat{\xi}}\right)^2} \gamma(\hat{\xi}) \, d\hat{\xi} \quad (11a)$$

$$Z_{\text{im}}^{\text{DRT}}(\xi) = 2\pi f L_0 - \int_{-\infty}^{\infty} \frac{2\pi e^{\xi - \hat{\xi}}}{1 + \left(2\pi e^{\xi - \hat{\xi}}\right)^2} \gamma(\hat{\xi}) \, d\hat{\xi} \quad (11b)$$

We indicate $\gamma(\xi)$ as the DRT, which is interchangeably denoted with a notational abuse as $\gamma(\xi)$, $\gamma(\log \tau)$, or $\gamma(\log f)$. We must stress that to keep the notation compact we will use ξ in the ensuing formulas. A similar abuse of notation will be used for $Z^{\text{DRT}}(f)$, which is interchangeably indicated as $Z^{\text{DRT}}(f)$ or $Z^{\text{DRT}}(\xi)$. Without loss of generality [71], we will start our discussion by dropping drop R_{∞} and L_0 to rewrite (11) as follows:

$$Z^{\text{DRT}}(\xi) = \mathcal{L}_{\xi}^{\text{re}}(\gamma(\xi)) + i\mathcal{L}_{\xi}^{\text{im}}(\gamma(\xi)) \quad (12)$$

where the two functionals $\mathcal{L}_{\xi}^{\text{re}}(\cdot)$ and $\mathcal{L}_{\xi}^{\text{im}}(\cdot)$ are defined as

$$\mathcal{L}_{\xi}^{\text{re}}(\cdot) = \int_{-\infty}^{\infty} \frac{1}{1 + \left(2\pi e^{\xi - \hat{\xi}}\right)^2} (\cdot) \, d\hat{\xi} \quad (13a)$$

$$\mathcal{L}_{\xi}^{\text{im}}(\cdot) = - \int_{-\infty}^{\infty} \frac{2\pi e^{\xi - \hat{\xi}}}{1 + \left(2\pi e^{\xi - \hat{\xi}}\right)^2} (\cdot) \, d\hat{\xi} \quad (13b)$$

100

2.3. The GP Distribution of Relaxation Times (GP-DRT)

In this section we recast the DRT model probabilistically using GPs. As already outlined above, we assume that $\gamma(\xi)$ is a latent GP. Formally, as the functionals defined in (13) to $\gamma(\xi)$ are applied, $Z^{\text{DRT}}(\xi)$ is generated via (12). As reported in Section 2.1.2, it follows that $Z^{\text{DRT}}(\xi)$ is also a GP because GPs are closed under linear
 105 functionals [67, 69], and since $Z^{\text{DRT}}(\xi)$ is derived from $\gamma(\xi)$, the two are correlated. Within this modeling framework, if the impedance data at certain frequencies is given, then one can estimate the latent (or hidden) variable $\gamma(\xi)$ at those frequencies. Since $\gamma(\xi)$ and $Z^{\text{DRT}}(\xi)$ are correlated GPs, one can predict both the DRT and the impedance at any new log-frequency ξ_{\star} . We should note that the GP-DRT approach has several advantages over other DRT regression methods because:

- 110 1. We can use the GP-DRT to conduct prediction. In other words, the mean and standard deviation of both impedance and DRT can be computed at frequencies other than those measured experimentally;
2. The hyperparameters of the GP-DRT model can be selected rationally by maximizing the experimental evidence as will be discussed in Section 2.3.4.

For technical reasons, which will be illustrated at the end of this section, we will only use the imaginary
 115 part of the impedance to estimate the DRT and to perform predictions. From a practical perspective, we will
 leverage multivariate Gaussian RVs, especially their conditioning and marginalization. Several useful properties of
 multivariate Gaussians are given in Appendix A, which the reader is recommended to read.

2.3.1. Basics

We start by considering the imaginary part of the impedance and the corresponding functional (13b). First, we
 120 assume that $\gamma(\xi)$ is a GP defined as

$$\gamma(\xi) \sim \mathcal{GP}(0, k(\xi, \xi')) \quad (14)$$

Since $Z_{\text{im}}^{\text{DRT}}(\xi) = \mathcal{L}_{\xi}^{\text{im}}(\gamma(\xi))$, see (12), it follows that both $\gamma(\xi)$ and $Z_{\text{im}}^{\text{DRT}}(\xi)$ are GPs with

$$\begin{pmatrix} \gamma(\xi) \\ Z_{\text{im}}^{\text{DRT}}(\xi) \end{pmatrix} \sim \mathcal{GP} \left(\mathbf{0}, \begin{pmatrix} k(\xi, \xi') & \mathcal{L}_{\xi'}^{\text{im}}(k(\xi, \xi')) \\ \mathcal{L}_{\xi}^{\text{im}}k(\xi, \xi') & \mathcal{L}_{\xi'}^{\text{im}}(\mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi')))) \end{pmatrix} \right) \quad (15)$$

It is then supposed that the measured impedance is affected by random errors, i.e.,

$$Z_{\text{im}}^{\text{exp}}(\xi) = Z_{\text{im}}^{\text{DRT}}(\xi) + \varepsilon \quad (16)$$

where $\varepsilon \sim \mathcal{N}(0, \sigma_n^2)$. All errors are taken to be independent and identically distributed (i.i.d.). Furthermore, we
 assume to have N observations, which are entered in a random vector $(\mathbf{Z}_{\text{im}}^{\text{exp}})_n = Z_{\text{im}}^{\text{exp}}(\xi_n)$ with $\xi_n = \log f_n$ and
 125 $n = 1, 2, \dots, N$. The latent variable at the measured frequencies $\boldsymbol{\xi} = (\xi_1, \xi_2, \dots, \xi_N)^\top$ is taken to be a random
 vector such that $(\boldsymbol{\gamma})_n = \gamma(\xi_n)$. Therefore, from (15) and (16), we can write following a line of reasoning similar to
 the one illustrated in Section 2.1.1 that $(\boldsymbol{\gamma}, \mathbf{Z}_{\text{im}}^{\text{exp}})^\top$ is a multivariate Gaussian RV, i.e.,

$$\begin{pmatrix} \boldsymbol{\gamma} \\ \mathbf{Z}_{\text{im}}^{\text{exp}} \end{pmatrix} \sim \mathcal{N} \left(\mathbf{0}, \begin{pmatrix} \mathbf{K} & \mathcal{L}_{\text{im}}\mathbf{K} \\ \mathcal{L}_{\text{im}}^\# \mathbf{K} & \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} \end{pmatrix} \right) \quad (17)$$

where \mathbf{I} is an $N \times N$ identity matrix, and the matrices \mathbf{K} , $\mathcal{L}_{\text{im}}\mathbf{K}$, $\mathcal{L}_{\text{im}}^2 \mathbf{K} \in \mathbb{R}^{N \times N}$ are defined as follows ($n, m = 1, \dots, N$):

$$(\mathbf{K})_{nm} = k(\xi_n, \xi_m) \quad (18a)$$

$$(\mathcal{L}_{\text{im}}\mathbf{K})_{nm} = \mathcal{L}_{\xi'}^{\text{im}}(k(\xi, \xi'))|_{\xi_n, \xi_m} \quad (18b)$$

$$(\mathcal{L}_{\text{im}}^\# \mathbf{K})_{nm} = \mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi'))|_{\xi_n, \xi_m} \quad (18c)$$

$$(\mathcal{L}_{\text{im}}^2 \mathbf{K})_{nm} = \mathcal{L}_{\xi'}^{\text{im}}(\mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi')))|_{\xi_n, \xi_m} \quad (18d)$$

From (18) and with an abuse of notation already used in this section, we can define the following matrix-valued functions (see Appendix B for details):

$$\mathbf{K} = \mathbf{K}(\boldsymbol{\xi}, \boldsymbol{\xi}) \quad (19a)$$

$$\mathcal{L}_{\text{im}} \mathbf{K} = \mathcal{L}_{\text{im}} \mathbf{K}(\boldsymbol{\xi}, \boldsymbol{\xi}) \quad (19b)$$

$$\mathcal{L}_{\text{im}}^{\#} \mathbf{K} = \mathcal{L}_{\text{im}}^{\#} \mathbf{K}(\boldsymbol{\xi}, \boldsymbol{\xi}) \quad (19c)$$

$$\mathcal{L}_{\text{im}}^2 \mathbf{K} = \mathcal{L}_{\text{im}}^2 \mathbf{K}(\boldsymbol{\xi}, \boldsymbol{\xi}) \quad (19d)$$

where we should note that, as shown in Appendix B, $\mathcal{L}_{\text{im}}^{\#} \mathbf{K} = \mathcal{L}_{\text{im}} \mathbf{K}^{\top}$.

2.3.2. Inversion

Using the GP formulation (15) and (16), we can estimate $\boldsymbol{\gamma}$ given the imaginary part of the experimental impedance. This is done by conditioning $\boldsymbol{\gamma}$ from (17) with respect to $\mathbf{Z}_{\text{im}}^{\text{exp}}$. In short, we can write that [67]

$$\boldsymbol{\gamma} | \mathbf{Z}_{\text{im}}^{\text{exp}} \sim \mathcal{N}(\boldsymbol{\mu}_{\boldsymbol{\gamma} | \mathbf{Z}_{\text{im}}^{\text{exp}}}, \boldsymbol{\Sigma}_{\boldsymbol{\gamma} | \mathbf{Z}_{\text{im}}^{\text{exp}}}) \quad (20)$$

where

$$\boldsymbol{\mu}_{\boldsymbol{\gamma} | \mathbf{Z}_{\text{im}}^{\text{exp}}} = \mathcal{L}_{\text{im}} \mathbf{K} (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{Z}_{\text{im}}^{\text{exp}} \quad (21a)$$

$$\boldsymbol{\Sigma}_{\boldsymbol{\gamma} | \mathbf{Z}_{\text{im}}^{\text{exp}}} = \mathbf{K} - \mathcal{L}_{\text{im}} \mathbf{K} (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathcal{L}_{\text{im}} \mathbf{K}^{\top} \quad (21b)$$

It should be stressed that the DRT (at the log-frequencies $\boldsymbol{\xi}$) is a Gaussian RV, whose mean and covariance can be computed analytically using (21). These formulas depend on 1) the kernel, $k(\boldsymbol{\xi}, \boldsymbol{\xi}')$; 2) the noise level, σ_n ; and 3) the experimental data, $\mathbf{Z}_{\text{im}}^{\text{exp}}$ (at the log-frequencies $\boldsymbol{\xi}$). In Section 2.3.4 we will show one method to select the hyperparameters, the parameters of the kernel and the σ_n .

2.3.3. Prediction

The GP-DRT can also be used to predict the impedance at a log-frequency $\boldsymbol{\xi}_{\star}$, which was not measured before. We can perform such a prediction by noting that, since both (15) and (16) hold, the joint distribution of latent $\boldsymbol{\gamma}$, target ($\mathbf{Z}_{\text{im}}^{\text{exp}}$), and predicted $\left(\boldsymbol{\gamma}(\boldsymbol{\xi}_{\star}), \mathbf{Z}_{\text{im}}^{\text{DRT}}(\boldsymbol{\xi}_{\star}) \right)^{\top}$ RVs follows a multivariate Gaussian distribution. Therefore, we can write

$$\begin{pmatrix} \boldsymbol{\gamma} \\ \mathbf{Z}_{\text{im}}^{\text{exp}} \\ \boldsymbol{\gamma}(\boldsymbol{\xi}_{\star}) \\ \mathbf{Z}_{\text{im}}^{\text{DRT}}(\boldsymbol{\xi}_{\star}) \end{pmatrix} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}) \quad (22)$$

where

$$\Sigma = \begin{pmatrix} \mathbf{K} & \mathcal{L}_{\text{im}} \mathbf{K} & \mathbf{K}(\xi, \xi_*) & \mathcal{L}_{\text{im}} \mathbf{K}(\xi, \xi_*) \\ \mathcal{L}_{\text{im}}^\# \mathbf{K} & \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} & \mathcal{L}_{\text{im}}^\# \mathbf{K}(\xi, \xi_*) & \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_*) \\ \mathbf{K}(\xi_*, \xi) & \mathcal{L}_{\text{im}} \mathbf{K}(\xi_*, \xi) & k(\xi_*, \xi_*) & \mathcal{L}_{\text{im}} k(\xi_*, \xi_*) \\ \mathcal{L}_{\text{im}}^\# \mathbf{K}(\xi_*, \xi) & \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi_*, \xi) & \mathcal{L}_{\text{im}}^\# k(\xi_*, \xi_*) & \mathcal{L}_{\text{im}}^2 k(\xi_*, \xi_*) \end{pmatrix} \quad (23)$$

It follows directly from (22) that

$$\begin{pmatrix} \mathbf{Z}_{\text{im}}^{\text{exp}} \\ Z_{\text{im}}^{\text{DRT}}(\xi_*) \end{pmatrix} \sim \mathcal{N} \left(\mathbf{0}, \begin{pmatrix} \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} & \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_*) \\ \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_*)^\top & \mathcal{L}_{\text{im}}^2 k(\xi_*, \xi_*) \end{pmatrix} \right) \quad (24)$$

Therefore $Z_{\text{im}}^{\text{DRT}}(\xi_*)$, *i.e.*, the imaginary part of the impedance predicted at ξ_* , is an RV that can be obtained from
145 the imaginary part of the experimental EIS data, $\mathbf{Z}_{\text{im}}^{\text{exp}}$, using the conditional distribution [68, 72]

$$Z_{\text{im}}^{\text{DRT}}(\xi_*) | \mathbf{Z}_{\text{im}}^{\text{exp}} \sim \mathcal{N} \left(\mu_{Z_{\text{im}}^{\text{DRT}}}, \Sigma_{Z_{\text{im}}^{\text{DRT}}} \right) \quad (25)$$

where

$$\mu_{Z_{\text{im}}^{\text{DRT}}} = \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_*)^\top (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{Z}_{\text{im}}^{\text{exp}} \quad (26a)$$

$$\Sigma_{Z_{\text{im}}^{\text{DRT}}} = \mathcal{L}_{\text{im}}^2 k(\xi_*, \xi_*) - \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_*)^\top (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_*) \quad (26b)$$

It also follows from (22) and (23) that

$$\begin{pmatrix} \mathbf{Z}_{\text{im}}^{\text{exp}} \\ \gamma(\xi_*) \end{pmatrix} \sim \mathcal{N} \left(\mathbf{0}, \begin{pmatrix} \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} & \mathcal{L}_{\text{im}} \mathbf{K}(\xi_*, \xi)^\top \\ \mathcal{L}_{\text{im}} \mathbf{K}(\xi_*, \xi) & k(\xi_*, \xi_*) \end{pmatrix} \right) \quad (27)$$

where we note $\mathcal{L}_{\text{im}}^\# \mathbf{K}(\xi, \xi_*) = \mathcal{L}_{\text{im}} \mathbf{K}(\xi_*, \xi)^\top$. Again, by conditioning we can write

$$\gamma(\xi_*) | \mathbf{Z}_{\text{im}}^{\text{exp}} \sim \mathcal{N}(\mu_{\gamma_*}, \Sigma_{\gamma_*}) \quad (28)$$

with

$$\mu_{\gamma_*} = \mathcal{L}_{\text{im}} \mathbf{K}(\xi_*, \xi) (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{Z}_{\text{im}}^{\text{exp}} \quad (29a)$$

$$\Sigma_{\gamma_*} = k(\xi_*, \xi_*) - \mathcal{L}_{\text{im}} \mathbf{K}(\xi_*, \xi) (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathcal{L}_{\text{im}} \mathbf{K}(\xi_*, \xi)^\top \quad (29b)$$

This derivation implies that the $\gamma(\xi_*)$ can also be predicted given the experimental data $\mathbf{Z}_{\text{im}}^{\text{exp}}$.

2.3.4. Selecting the Hyperparameters

150 As already illustrated in Section 2.3.2, the matrix formulas given above for means and covariances depend on the experimental data and the hyperparameters of the model. While during the data analysis phase there is little control over the experimental data, all hyperparameters can be chosen, including the kernel $k(\xi, \xi')$ and the (unknown) noise level σ_n . Hereon, we constrain the kernel to be a squared exponential, *i.e.*,

$$k(\xi, \xi') = \sigma_f^2 \exp \left(-\frac{1}{2\ell^2} (\xi - \xi')^2 \right) \quad (30)$$

and we will modify its two parameters, σ_f and ℓ . Therefore, the vector of hyperparameters of the GP-DRT is assumed to be $\boldsymbol{\theta} = \left(\sigma_n, \sigma_f, \ell \right)^\top$.

A $\boldsymbol{\theta}$ can be selected by maximizing the marginal likelihood, the probability, $p(\mathbf{Z}_{\text{im}}^{\text{exp}} | \boldsymbol{\xi}, \boldsymbol{\theta})^3$, of measuring the data, $\mathbf{Z}_{\text{im}}^{\text{exp}}$. The maximizing $\boldsymbol{\theta}$ is the one that would have most likely resulted in the measured experimental data. We note that $\mathbf{Z}_{\text{im}}^{\text{exp}} | \boldsymbol{\theta} \sim \mathcal{N}(0, \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})$. Therefore, we obtain the following marginal log-likelihood (MLL) [72]:

$$\begin{aligned} \log p(\mathbf{Z}_{\text{im}}^{\text{exp}} | \boldsymbol{\xi}, \boldsymbol{\theta}) &= -\frac{1}{2} \mathbf{Z}_{\text{im}}^{\text{exp} \top} (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{Z}_{\text{im}}^{\text{exp}} + \\ &\quad -\frac{1}{2} \log |\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I}| - \frac{N}{2} \log 2\pi \end{aligned} \quad (31)$$

We will call $L(\boldsymbol{\theta})$ the negative (and shifted) MLL (NMLL):

$$L(\boldsymbol{\theta}) = -\log p(\mathbf{Z}_{\text{im}}^{\text{exp}} | \boldsymbol{\xi}, \boldsymbol{\theta}) - \frac{N}{2} \log 2\pi \quad (32)$$

160 It follows that the experimental evidence is maximized for

$$\boldsymbol{\theta} = \arg \min_{\boldsymbol{\theta}'} L(\boldsymbol{\theta}') \quad (33)$$

We also note that, in order to minimize $L(\boldsymbol{\theta})$, one may use a gradient-based method which requires the computation of $\nabla L(\boldsymbol{\theta})$. This can be done analytically as shown in Appendix C.

³We emphasize pedantically the conditioning with respect to $\boldsymbol{\xi}$ and $\boldsymbol{\theta}$ as both parameters influence the evidence.

2.3.5. Comment

It would have been tempting to combine the real and imaginary parts of the impedance formally. We note that if the DRT model (12) and (14) hold, then the following also holds:

$$\begin{pmatrix} \gamma(\xi) \\ Z_{\text{re}}^{\text{DRT}}(\xi) \\ Z_{\text{im}}^{\text{DRT}}(\xi) \end{pmatrix} \sim \mathcal{GP} \left(\mathbf{0}, \begin{pmatrix} k(\xi, \xi') & \mathcal{L}_{\xi'}^{\text{re}}(k(\xi, \xi')) & \mathcal{L}_{\xi'}^{\text{im}}(k(\xi, \xi')) \\ \mathcal{L}_{\xi}^{\text{re}}(k(\xi, \xi')) & \mathcal{L}_{\xi'}^{\text{re}}(\mathcal{L}_{\xi}^{\text{re}}(k(\xi, \xi'))) & \mathcal{L}_{\xi'}^{\text{im}}(\mathcal{L}_{\xi}^{\text{re}}(k(\xi, \xi'))) \\ \mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi')) & \mathcal{L}_{\xi'}^{\text{re}}(\mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi'))) & \mathcal{L}_{\xi'}^{\text{im}}(\mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi'))) \end{pmatrix} \right) \quad (34)$$

However, we must remark that, as shown in Appendix B,

$$\mathcal{L}_{\xi'}^{\text{re}}(\mathcal{L}_{\xi}^{\text{re}}(k(\xi, \xi'))) = \infty \quad (35)$$

The covariance being infinite renders impractical the use of the real part of the impedance. While we will not attempt to use such a portion of the data, we will discuss in Section 4 how this issue could be overcome.

2.4. The GP-DRT with Inductance

In this section we are going to relax the hypothesis that $L_0 = 0$ used in (12), and, instead, set that

$$\begin{pmatrix} \gamma(\xi) \\ Z_{\text{im}}^{\text{DRT}}(\xi) \end{pmatrix} \sim L_0 \begin{pmatrix} 0 \\ 2\pi e^{\xi} \end{pmatrix} + \mathcal{GP} \left(\mathbf{0}, \begin{pmatrix} k(\xi, \xi') & \mathcal{L}_{\xi'}^{\text{im}}(k(\xi, \xi')) \\ \mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi')) & \mathcal{L}_{\xi'}^{\text{im}}(\mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi'))) \end{pmatrix} \right) \quad (36)$$

where L_0 is a normally distributed RV, *i.e.*, $L_0 \sim \mathcal{N}(0, \sigma_L^2)$, independent with respect to the right hand side's GP, which is identical to the GP defined in (15). If we integrate out the L_0 in (36), we can write [70, 71]

$$\begin{pmatrix} \gamma(\xi) \\ Z_{\text{im}}^{\text{DRT}}(\xi) \end{pmatrix} \sim \mathcal{GP} \left(\mathbf{0}, \begin{pmatrix} k(\xi, \xi') & \mathcal{L}_{\xi'}^{\text{im}}(k(\xi, \xi')) \\ \mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi')) & \mathcal{L}_{\xi'}^{\text{im}}(\mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi'))) + \sigma_L^2 h(\xi)h(\xi') \end{pmatrix} \right) \quad (37)$$

where $h(\xi) = 2\pi e^{\xi}$. Therefore, using the same procedure used for (17), we obtain

$$\begin{pmatrix} \gamma \\ \mathbf{Z}_{\text{im}}^{\text{exp}} \end{pmatrix} \sim \mathcal{N} \left(0, \begin{pmatrix} \mathbf{K} & \mathcal{L}_{\text{im}} \mathbf{K} \\ \mathcal{L}_{\text{im}}^{\#} \mathbf{K} & \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^{\top} \end{pmatrix} \right) \quad (38)$$

where $\mathbf{h} = \left(h(\xi_1), h(\xi_2), \dots, h(\xi_N) \right)^\top$. With an analogous procedure as the one used to derive (22) and (23), we
175 can also write

$$\begin{pmatrix} \gamma \\ \mathbf{Z}_{\text{im}}^{\text{exp}} \\ \gamma(\xi_\star) \\ Z_{\text{im}}^{\text{DRT}}(\xi_\star) \end{pmatrix} \sim \mathcal{N}(0, \Sigma) \quad (39)$$

where

$$\Sigma = \begin{pmatrix} \mathbf{K} & \mathcal{L}_{\text{im}} \mathbf{K} & \mathbf{K}(\xi, \xi_\star) & \mathcal{L}_{\text{im}} \mathbf{K}(\xi, \xi_\star) \\ \mathcal{L}_{\text{im}}^\# \mathbf{K} & \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^\top & \mathcal{L}_{\text{im}}^\# \mathbf{K}(\xi, \xi_\star) & \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_\star) + \sigma_L^2 h(\xi_\star) \mathbf{h} \\ \mathbf{K}(\xi_\star, \xi) & \mathcal{L}_{\text{im}} \mathbf{K}(\xi_\star, \xi) & k(\xi_\star, \xi_\star) & \mathcal{L}_{\text{im}} k(\xi_\star, \xi_\star) \\ \mathcal{L}_{\text{im}}^\# \mathbf{K}(\xi_\star, \xi) & \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi_\star, \xi) + \sigma_L^2 h(\xi_\star) \mathbf{h}^\top & \mathcal{L}_{\text{im}}^\# k(\xi_\star, \xi_\star) & \mathcal{L}_{\text{im}}^2 k(\xi_\star, \xi_\star) + \sigma_L^2 h(\xi_\star)^2 \end{pmatrix} \quad (40)$$

It follows directly from (39) and (40) that

$$\begin{pmatrix} \mathbf{Z}_{\text{im}}^{\text{exp}} \\ Z_{\text{im}}^{\text{DRT}}(\xi_\star) \end{pmatrix} \sim \mathcal{N} \left(\mathbf{0}, \begin{pmatrix} \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^\top & \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_\star) + \sigma_L^2 h(\xi_\star) \mathbf{h} \\ \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_\star)^\top + \sigma_L^2 h(\xi_\star) \mathbf{h}^\top & \mathcal{L}_{\text{im}}^2 k(\xi_\star, \xi_\star) + \sigma_L^2 h(\xi_\star)^2 \end{pmatrix} \right) \quad (41)$$

By conditioning $Z_{\text{im}}^{\text{DRT}}(\xi_\star)$ to the data, we can write [71]

$$Z_{\text{im}}^{\text{DRT}}(\xi_\star) | \mathbf{Z}_{\text{im}}^{\text{exp}} \sim \mathcal{N} \left(\mu_{Z_{\text{im}}^\star}^L, \Sigma_{Z_{\text{im}}^\star}^L \right) \quad (42)$$

where

$$\mu_{Z_{\text{im}}^\star}^L = h(\xi_\star) \bar{L}_0 + \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi, \xi_\star)^\top (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} (\mathbf{Z}_{\text{im}}^{\text{exp}} - \mathbf{h}^\top \bar{L}_0) \quad (43a)$$

$$\Sigma_{Z_{\text{im}}^\star}^L = \Sigma_{Z_{\text{im}}^\star}^{\text{DRT}} + \frac{R^2}{\sigma_L^{-2} + \mathbf{h}^\top (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{h}} \quad (43b)$$

with

$$\bar{L}_0 = \frac{\mathbf{h}^\top (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{Z}_{\text{im}}^{\text{exp}}}{\sigma_L^{-2} + \mathbf{h}^\top (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{h}} \quad (44a)$$

$$R = h(\xi_\star) - \mathbf{h} (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathcal{L}_{\text{im}} \mathbf{K}(\xi_\star, \xi)^\top \quad (44b)$$

Similarly, we obtain that

$$\begin{pmatrix} \mathbf{Z}_{\text{im}}^{\text{exp}} \\ \gamma(\xi_\star) \end{pmatrix} \sim \mathcal{N} \left(\mathbf{0}, \begin{pmatrix} \mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^\top & \mathcal{L}_{\text{im}} \mathbf{K}(\xi_\star, \xi)^\top \\ \mathcal{L}_{\text{im}} \mathbf{K}(\xi_\star, \xi) & k(\xi_\star, \xi_\star) \end{pmatrix} \right) \quad (45)$$

180 therefore

$$\gamma(\xi_\star) | \mathbf{Z}_{\text{im}}^{\text{exp}} \sim \mathcal{N}(\mu_{\gamma_\star}, \Sigma_{\gamma_\star}) \quad (46)$$

with

$$\mu_{\gamma_\star} = \mathcal{L}_{\text{im}} \mathbf{K}(\xi_\star, \xi) (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^\top)^{-1} \mathbf{Z}_{\text{im}}^{\text{exp}} \quad (47a)$$

$$\Sigma_{\gamma_\star} = k(\xi_\star, \xi_\star) - \mathcal{L}_{\text{im}} \mathbf{K}(\xi_\star, \xi) (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^\top)^{-1} \mathcal{L}_{\text{im}} \mathbf{K}(\xi_\star, \xi)^\top \quad (47b)$$

As shown previously in Section 2.3.4, we can also derive the marginal log-likelihood (MLL), which, under the assumptions of this subsection, is given by

$$\begin{aligned} \log p(\mathbf{Z}_{\text{im}}^{\text{exp}} | \xi, \theta) = & -\frac{1}{2} \mathbf{Z}_{\text{im}}^{\text{exp}^\top} (\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^\top)^{-1} \mathbf{Z}_{\text{im}}^{\text{exp}} + \\ & -\frac{1}{2} \log |\mathcal{L}_{\text{im}}^2 \mathbf{K} + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^\top| - \frac{N}{2} \log 2\pi \end{aligned} \quad (48)$$

3. Results

The GP-DRT model will be tested using both synthetic and real experimental data. First, the synthetic experiments are analyzed to test the consistency of the methodology. Specifically, since the exact impedance and DRT are both known a priori, it will be verified that the GP-DRT can recover both quantities. In doing that, the influence of the hyperparameters on both inversion and prediction are illustrated. Furthermore, it will be shown that these hyperparameters can be chosen optimally. It is also demonstrated that the GP-DRT is robust to noise, missing data, and overlapping features in the timescale distribution. As a second step, the GP-DRT framework will be applied to actual experiments in order to gauge its capability to handle real data. In particular, the GP-DRT model is benchmarked against the previously developed Bayesian DRT methodology [49, 57, 73].

3.1. Synthetic Experiments

In this subsection the GP-DRT model is tested against synthetic experiments to ensure its consistency. The influence of the hyperparameters is also illustrated. Further, the GP-DRT is shown to be able to consistently handle severe noise, spectral truncation, bimodal timescale distributions, and inductive features. Before starting a systematic analysis of the synthetic and real EIS data, we recall that we will use interchangeably $\gamma(\log \tau)$, $\gamma(\log f)$, or $\gamma(\xi)$ and that a similar notational abuse also applies to $Z_{\text{im}}^{\text{DRT}}(f)$ and $Z_{\text{im}}^{\text{DRT}}(\xi)$.

3.1.1. Exact impedance

The analysis of the synthetic data is primarily based on the impedance of a ZARC element consisting of a resistance placed in parallel to a constant phase element (CPE) [74]. The $Z^{\text{exact}}(f)$ is therefore given by

$$Z^{\text{exact}}(f) = R_{\infty} + \frac{1}{\frac{1}{R_{\text{ct}}} + C (i2\pi f)^{\phi}} \quad (49)$$

where $C = \frac{\tau_0^{\phi}}{R_{\text{ct}}}$ and the specific parameters used are shown in Table 1. As is well known, the DRT of (49) is given by [75]

$$\gamma(\log \tau) = \frac{R_{\text{ct}}}{2\pi} \frac{\sin((1-\phi)\pi)}{\cosh(\phi \log(\tau/\tau_0)) - \cos(\pi(1-\phi))} \quad (50)$$

In Figure 2, we report the Nyquist representation of the impedance, panel (a), and the DRT, panel (b). This shows both the exact impedance given by (49) and its noise-corrupted counterpart $Z^{\text{exp}}(f)$ given by (16), where we set $\sigma_n = \sigma_n^{\text{exp}} = 0.1 \Omega^{1/2}$.⁴ We recall once more that the current version of the GP-DRT model does not use the real part of the impedance data.

Table 1: Parameters used for the exact impedance model.

Parameter	Numerical Value
R_{∞}	10 Ω
R_{ct}	50 Ω
τ_0	1 s
τ_1	0.1 s
τ_2	10 s
ϕ	0.8
L_0	5.0×10^{-4} H

3.1.2. Qualitative Considerations

Starting from the synthetic data, we illustrate the influence of the hyperparameters on the recovery of the latent DRT, $\gamma(\xi)$, and the imaginary part of the impedance $Z_{\text{im}}^{\text{DRT}}(f)$.

First we set $\sigma_f = 1$ and $\sigma_n = \sigma_n^{\text{exp}}$. As shown in Figure 3, changing the length scale ℓ of the kernel has a dramatic influence on the recovered $\gamma(\xi)$ and $Z_{\text{im}}^{\text{DRT}}(f)$. In the left-hand panels, we report the exact and the inverted DRT given by equation (50) and (20), respectively. The right-hand panels depict instead the imaginary part of the impedance including its exact value, the synthetic experiment, and the recovered value from (24). As the standard deviations are small, only the mean (red line) is visible.

A small ℓ (here we have $\ell = 10^{-2}$), see panels (a) and (b) of Figure 3, is indicative of only short range log-frequency correlations (30). This choice results in: 1) a rather large variance as indicated by the shaded area around

⁴We note that this expression is an abuse of notation because σ_n is *de facto* an hyperparameter, while σ_n^{exp} is the amount of noise given to the synthetic experiment.

the mean (red line), see Figure 3 (a); and 2) a significant discrepancy compared to the experimental impedance, see Figure 3 (b). The DRT peak is lower than the exact one and does not result in significant oscillations at either low or high frequencies. Raising the value of ℓ to 1 gives a closer matching of the peak height in the DRT, see Figure 3 (c), and an improved recovery of the imaginary part of the impedance as shown in Figure 3 (d). It also leads to a greater confidence in the recovered DRT as shown by the far smaller shaded area. However, oscillations are stronger at both low and high log-frequencies. This is in contrast with the $\ell = 10^{-2}$ case, where the shorter-range log-frequency correlations hamper the oscillations. Increasing ℓ by an order of magnitude to 10 has a deleterious impact on both the inverted $\gamma(\xi)$, see Figure 3 (e), and the recovered impedance $Z_{\text{im}}^{\text{DRT}}(f)$, see Figure 3 (f). Under these circumstances, the correlations are so broad that both $\gamma(\xi)$ and $Z_{\text{im}}^{\text{DRT}}(f)$ effectively flatten out.

To better understand the results presented above, let us directly inspect \mathbf{K} and $\mathcal{L}^2\mathbf{K}$, two of the important matrices used in Section 2.3 and given by (18). The parameter ℓ strongly influences both matrices, as shown in Figure 4. Choosing a relative short cross-correlation scale ($\ell = 10^{-2}$) results in a diagonally dominated \mathbf{K} matrix, see Figure 4 (a). The fact that \mathbf{K} is mostly diagonal implies that the value $\gamma(\xi)$ at a certain log-frequency ξ is only influenced by a small number of ξ values directly adjacent to it. Applying the functional (13b) twice gives the $\mathcal{L}^2\mathbf{K}$ as illustrated in (18d). Since the integral is convolutive in nature, the number of non-zero entries in the $\mathcal{L}^2\mathbf{K}$ matrix increases relative to those in \mathbf{K} , see Figure 4 (b). This means that $\mathcal{L}^2\mathbf{K}$ implies far broader correlations than \mathbf{K} . In other words, while the DRT may not strongly cross-correlated across the log-frequencies for low enough ℓ , the values of the $Z_{\text{im}}^{\text{DRT}}(f)$ depend on each other across a far broader spectrum. As shown in Figure 4 (c) and (d), increasing ℓ to 1 broadens $\mathcal{L}^2\mathbf{K}$ more strongly compared to the $\ell = 10^{-2}$ case. This is also in agreement with intuition and the results that relate to Figure 3 (c) and (d). As already illustrated when discussing Figure 3 (c) and (d), increasing ℓ to 1 has a positive impact on the recovery of $Z_{\text{im}}^{\text{DRT}}(f)$ but yields stronger oscillations in the $\gamma(\xi)$.

3.1.3. Hyperparameter Optimization

Table 2: Optimal hyperparameters obtained by minimizing the NMLL function $L(\theta)$.

Case	Description		σ_n	σ_f	ℓ	σ_L	Figure
1	Hyperparameter Optimization		8.44×10^{-2}	5.44	0.89		5 (c), 5 (d)
2a	Increased Experimental	$\sigma_n^{\text{exp}} = 1.0 \Omega^{1/2}$	0.83	5.41	1.25		7 (c), 7 (e)
2b	Errors	$\sigma_n^{\text{exp}} = 3.0 \Omega^{1/2}$	2.45	5.33	1.40		7 (d), 7 (f)
3a	Truncated Data	at 10^{-3} Hz	0.10	5.80	0.94		8 (c), 8 (e)
3b		at 10^{-2} Hz	0.11	6.03	1.02		8 (d), 8 (f)
4a	Overlapping Timescales ($\tau_1 = 0.1$ s)	$\tau_2 = 10$ s	8.24×10^{-2}	7.81	0.86		9 (c), 9 (e)
4b		$\tau_2 = 1$ s	8.30×10^{-2}	8.17	0.83		9 (d), 9 (f)
5	Inductance Added		0.42	5.64	1.22	5.07×10^{-4}	10
6	SOFC Experiment		3.89×10^{-4}	3.85×10^{-3}	1.30	5.35×10^{-7}	11
7	LIB Experiment		1.37×10^{-4}	5.09×10^{-3}	0.37	6.37×10^{-7}	12

We show now how the hyperparameters can be optimized based on the experimental data. We will not only change ℓ parametrically as done in Section 3.1.2 but we will also set all values in the vector $\theta = (\sigma_n, \sigma_f, \ell)$. For illustration purposes, we start by varying only two elements of θ ($\sigma_f = 1$) and show the $L(\theta)$ given by (32) as a function

of σ_n and ℓ . We recall that, as explained in the Section 2.3.4, $L(\boldsymbol{\theta})$ is closely linked to the maximum likelihood and minimizing this function corresponds to maximizing the experimental evidence. At the minimum the model output, $Z_{\text{im}}^{\text{DRT}}(f)$, is closest to the synthetic experiment, $Z_{\text{im}}^{\text{exp}}(f)$. In other words, the minimized hyperparameters are the ones that best comply with the data, which is illustrated this in Figure 5. From Figure 5 (a), we observe that the minimum in the (ℓ, σ_n) plane is obtained for $\sigma_n \approx \sigma_n^{\text{exp}}$, consistently with the value of the added noise. The ℓ is approximately equal to 1, the value used for some of the results presented in Section 3.1.2 above. We then set (ℓ, σ_n) to be equal to its value at the star symbol in Figure 5 (a) and seek a σ_f which can further minimize the $L(\boldsymbol{\theta})$. Figure 5 (b) shows that a rather sharp minimum can be located at $\sigma_f \approx 5$ further improving the adherence of the model with the synthetic experiment. However, it must be noted that this is not the true minimum of $L(\boldsymbol{\theta})$. The latter can be instead obtained by minimizing all entries of the vector $\boldsymbol{\theta}$ simultaneously. The obtained value $\boldsymbol{\theta}$ shown in Table 2 (case 1) gives the $\gamma(\xi)$ and $Z_{\text{im}}^{\text{DRT}}(f)$ shown in Figure 5 (c) and (d), respectively. Unsurprisingly, this value improves (at least visually) the recovery of the imaginary part of the impedance $Z_{\text{im}}^{\text{DRT}}(f)$, see Figure 5 (d). Minimizing $L(\boldsymbol{\theta})$ yields the latent DRT, $\gamma(\xi)$, shown in Figure 5 (c). Fringes of higher amplitude are present compared to those observed for Figure 3 (c). The emergence of these fringes is a direct result of the minimization strategy, which does not aim at optimizing the latent (or unseen) function $\gamma(\xi)$, but rather optimizes the GP-DRT model parameters with respect to the given experimental evidence $Z_{\text{im}}^{\text{exp}}(f)$.

3.1.4. Influence of Experimental Errors

The above discussion has shown that by using the imaginary part of the EIS data, one is able to recover the latent function, $\gamma(\xi)$. Since we have used only one computational experiment, we now wish to see if the qualitative conclusions drawn above still hold for more synthetic experiments and for larger experimental noise, σ_n^{exp} . To this end, 1,000 synthetic experiments were generated using (16) for each $\sigma_n^{\text{exp}}/\Omega^{1/2} = 0.1, 0.2, \dots, 1.0$. After generating each synthetic experiment, the optimal $\boldsymbol{\theta}$ by minimizing the NMLL function $L(\boldsymbol{\theta})$ was computed. Figure 6 presents a box plot of the optimal $\boldsymbol{\theta}$'s over 10,000 stochastic experiments. The box extends from the 25% and 75% quartiles with the notch being the median. As seen in Figure 6 (a), minimizing the NMLL leads to an accurate recovery of σ_n^{exp} by σ_n (the actual “experimental” values are plotted as the dashed line). Unsurprisingly, as we increase σ_n^{exp} , the uncertainty on σ_n increases as evidenced by the larger box. The increased uncertainty of σ_n also holds for other two parameters ℓ and σ_f .

Figure 7 explicitly reports the synthetic impedance $Z_{\text{im}}^{\text{exp}}(f)$, the inverted $\gamma(\xi)$, and the fitted $Z_{\text{im}}^{\text{DRT}}(f)$ for two synthetic experiments with $\sigma_n^{\text{exp}} = 1$ (panels (a), (c), and (e)) and $\sigma_n^{\text{exp}} = 3$ (panels (d), (f), and (h)). The optimal hyperparameters for these two experiments are also reported in Table 2 as case 2a and 2b, respectively. As σ_n^{exp} increases from 0.1 (Figure 2) to 1 and 3, the impedance is far noisier, leading to larger uncertainties (gray regions) relative to $\gamma(\xi)$ and $Z_{\text{im}}^{\text{DRT}}(f)$. We must note two significant results: 1) in spite of the significant noise, the GP-DRT is still able to recover the correct mean impedance; and 2) the enlarged experimental uncertainty σ_n^{exp} is encoded directly in the model, which can quantitatively assess it by selecting (via the minimization of $L(\boldsymbol{\theta})$) the

corresponding hyperparameter σ_n .

3.1.5. Truncated Data and Prediction

We now test if truncating the data at a certain frequency can still allow us to estimate $\gamma(\xi)$ and $Z_{\text{im}}^{\text{DRT}}(f)$ reasonably well. The same synthetic impedance data reported in Figure 2 is used but it is truncated at 10^{-3} Hz, see Figure 8 (a). The GP-DRT can be used to predict the $\gamma(\xi)$ beyond the experimental range (for $f < 10^{-3}$ Hz) as shown in Figure 8 (c). While the predicted mean does not deviate significantly from the exact values, the standard deviation is particularly large, suggesting significant uncertainties. These uncertainties start before (at $f \approx 10^{-2}$ Hz) the enforced cut-off (at $f = 10^{-3}$ Hz) and broaden significantly when approaching it. In contrast, the recovered $Z_{\text{im}}^{\text{DRT}}(f)$ appears to be compliant with the synthetic experiment only for $f \geq 10^{-3}$ Hz, see Figure 8 (e). At lower frequencies, consistently with intuition, uncertainties increase and result in a widening of the credibility band.

It should be stressed again that the predicted values, both the hidden $\gamma(\xi)$ and the prediction $Z_{\text{im}}^{\text{DRT}}(f)$, are less reliable outside the measurement region. The same issues also emerge for EIS data truncated at 10^{-2} Hz. It is worth noting that, unsurprisingly, the optimal values of θ , which are reported in Table 2 as case 3a and 3b, are different from the ones used in case 1 in Table 2. Cutting off the impedance at low frequencies results in additional oscillations of the DRT at high frequencies, see Figure 8 (c) and (d) for $f > 10$ Hz. However, such fringes were not obviously present in untruncated data as illustrated in Figure 5 (c). The larger the cutoff the more strongly the high frequency region is affected. This underpins the nature of the functional $\mathcal{L}_{\text{im}}(\cdot)$ that being a convolution leads to significant correlations in frequency space, as is apparent from (13b). Again, this result is consistent with the discussion in Section 3.1.2 regarding \mathbf{K} and $\mathcal{L}^2\mathbf{K}$.

3.1.6. Overlapping Frequencies

We will further test if the GP-DRT model can recover overlapping features by summing two ZARCs, which have the following impedance response [49, 57, 73]

$$Z^{\text{exact}}(f) = 2R_{\infty} + \frac{1}{\frac{1}{R_{\text{ct}}} + C_1 (i2\pi f)^{\phi}} + \frac{1}{\frac{1}{R_{\text{ct}}} + C_2 (i2\pi f)^{\phi}} \quad (51)$$

with $C_1 = \frac{\tau_1^{\phi}}{R_{\text{ct}}}$, $C_2 = \frac{\tau_2^{\phi}}{R_{\text{ct}}}$ and specific parameters reported in Table 1. To generate the synthetic data shown in left-hand panels of Figure 9, σ_n^{exp} is set to $0.1 \Omega^{1/2}$.

We first study separated timescales with $\tau_1 = 0.1$ s and $\tau_2 = 10$ s. The Nyquist plot reported in Figure 9 (a) clearly shows two semi-circles. The DRT obtained by (50) also depicts two well separated main peaks corresponding to above two different timescales, see Figure 9 (c). By minimizing the NMLL function $L(\theta)$, the optimal hyperparameters are obtained as listed in Table 2 and the recovered $\gamma(\xi)$ is also plotted in Figure 9 (c). We find that the

GP-DRT well fits the two main peaks of $\gamma(\xi)$ and estimates the mean of $\gamma(\xi)$ at higher frequencies for $f > 10^{-2}$ Hz. The uncertainties become higher at lower frequencies, which is also visible for a single ZARC model, see Figure 5 (c).

To further test the capability of the GP-DRT model to recover overlapping DRT features, we reduce τ_2 by an order of magnitude and keep τ_1 constant ($\tau_1 = 0.1$ s and $\tau_2 = 1.0$ s). As shown in Figure 9 (b), the Nyquist plot appears visually as a single depressed semi-circle. Further, the two peaks of the exact $\gamma(\xi)$ are much closer to each other, see Figure 9 (d). The GP-DRT model with the hyperparameters given in Table 2 (case 4a and 4b) obtained by minimizing $L(\theta)$ can still capture the key features of the DRT and match the exact $\gamma(\xi)$ well. However, similar to the $\tau_2 = 10$ s case of Figure 9 (c), oscillations with high variance appear at low frequencies. The recovered imaginary impedance $Z_{\text{im}}^{\text{DRT}}(f)$ for both cases are shown in Figure 9 (e) and (f), which appear to adhere remarkably well to the exact value. While many more simulations will be needed in the future, these results suggest that the GP-DRT model can recover the exact DRT and the impedance even if there are overlapping features.

3.1.7. Inductance

We then use the theory of Section 2.4 to obtain the DRT of the ZARC model (49) with an added inductance L_0 . This corresponds to the following exact impedance:

$$Z^{\text{exact}}(f) = i2\pi f L_0 + R_\infty + \frac{1}{\frac{1}{R_{\text{ct}}} + C(i2\pi f)^\phi} \quad (52)$$

In Figure 10 (a) we report the $Z^{\text{exp}}(f)$ for $\sigma_n^{\text{exp}} = 0.1 \Omega^{1/2}$. 10,000 synthetic experiments (1,000 experiments for each σ_n^{exp}) were carried out in the same spirit as the ones conducted in Section 3.1.4. The optimal hyperparameters σ_n and σ_L listed in Table 2 (case 5) can be used to estimate \bar{L}_0 , see equation (44). The results of these simulations are reported as a boxplot in Figure 10 (b). The average \bar{L}_0 consistently matches the exact value and its confidence region broadens as the noise increases, highlighting the ability of the GP-DRT to handle inductive features. The recovered DRT and impedance shown in Figure 10 (c) and Figure 10 (d), respectively, match well with the exact noise-free values.

3.2. Real Experiments

3.2.1. SOFC Impedance

We analyzed the EIS data obtained by testing a symmetrical cell with a $\text{Ba}_{0.95}\text{La}_{0.05}\text{Fe}_{0.95}\text{P}_{0.05}\text{O}_{3-\delta}$ electrode and 15% Samarium-doped ceria as the electrolyte with an active area of approximately 1 cm^2 [76]. The symmetrical cell's EIS spectrum shown in Figure 11 (a), was measured at 700°C in synthetic air ($p_{\text{O}_2} = 0.21 \text{ atm}$) over frequencies from 0.1 Hz to $2.47 \times 10^4 \text{ Hz}$ with 15 points per decade (ppd). The experimental data was first modeled as a single ZARC circuit, whose parameters are reported in Table 3. The Nyquist plot of the EIS generated by the chosen ECM is also shown in Figure 11 (a). Using the ZARC model, $\gamma^{\text{ref}}(\xi)$ can be calculated using (50), see Figure 11

(b). Following the same procedure used in the Section 3.1.7, we minimize the NMLL, $L(\theta)$, to obtain the optimal hyperparameters used to recover the latent $\gamma(\xi)$ shown in Figure 11 (b). It is noted that the GP-DRT matches well to $\gamma^{\text{ref}}(\xi)$'s main peak, which is located at $f \approx 10^4$ Hz. The $\gamma(\xi)$'s credibility is generally high but decreases away from the peak. In addition, the GP-DRT estimates \bar{L}_0 as 5.31×10^{-7} H, which is much close to the value fitted by ECM as listed in Table 3. We also conducted Bayesian RR [49] to compare the recovered $\gamma(\xi)$ against that obtained by GP-DRT. As illustrated in Figure 11 (c), the RR deconvolution matches the $\gamma^{\text{ref}}(\xi)$ well and displays a credibility higher than that of the GP-DRT. Lastly, Figure 11 (d) shows the reconstructed imaginary parts of the EIS data by GP-DRT and RR. The two deconvolutions overlap and fit the $Z_{\text{im}}^{\text{exp}}(f)$ well. We must stress that, while the $Z_{\text{im}}(f)$ obtained using the GP-DRT is a GP with a narrow credibility band, its Bayesian RR counterpart is simply a function obtained by mapping of the maximum a posteriori prediction (the black line of Figure 11 (c)) to the impedance.

Table 3: ECM parameters obtained by fitting the EIS spectrum of the SOFC shown in Figure 11.

Parameter	Numerical Value
R_{∞}	1.42 Ω
R_{ct}	8.41×10^{-2} Ω
τ_0	1.88×10^{-4} s
ϕ	0.64
L_0	5.20×10^{-7} H

345

3.2.2. Commercial LIB Spectra

We used the GP-DRT model to analyze a previously reported EIS spectrum of a commercial lithium-ion battery (LIB) [57]. A commercial LIB (LiCoO₂-Ansmann 18650) was tested at 25% state of charge at room temperature. The EIS, which is reported in Figure 12 (a), was collected from 5 mHz to 600 Hz. We chose this spectrum because it provides a challenging test for the GP-DRT model [66, 77]. We first fitted the measured EIS to an ECM composed of 3 ZARCs:

$$Z_{\text{ECM}}(f) = i2\pi f L_0 + R_{\infty} + \frac{1}{\frac{1}{R_{\text{ct},1}} + C_1 (i2\pi f)^{\phi_1}} + \frac{1}{\frac{1}{R_{\text{ct},2}} + C_2 (i2\pi f)^{\phi_2}} + \frac{1}{\frac{1}{R_{\text{ct},3}} + C_3 (i2\pi f)^{\phi_3}} \quad (53)$$

with the regressed parameters listed in Table 4. The DRT obtained by (50) is the $\gamma^{\text{ref}}(\xi)$ plotted in Figure 12 (b) and (c) as a reference. As illustrated in Figure 12 (b), the recovered $\gamma(\xi)$ by the GP-DRT model captures the $\gamma^{\text{ref}}(\xi)$'s main peaks and values. However, the mean value of the $\gamma(\xi)$ has stronger oscillations and a broader credibility region. The inductance \bar{L}_0 estimated by the GP-DRT is 5.20×10^{-7} H, a value matching the one obtained by the ECM fitting, see Table 4. Following our earlier publications [49, 73], we also deconvolved the LIB spectrum using Bayesian RR to estimate the $\gamma(\xi)$, see Figure 12 (c). It is noted that, unlike the GP-DRT framework, the Bayesian RR method has difficulty in matching well to the shape and the position of the main peaks of $\gamma^{\text{ref}}(\xi)$.

The recovered imaginary part of the impedance $Z_{\text{im}}^{\text{DRT}}(f)$ is shown in Figure 12 (d) together with the imaginary

experimental impedance $Z_{\text{im}}^{\text{exp}}(f)$. The GP-DRT approach matches the experimental data with a high credibility. In contrast, Bayesian RR shows clear discrepancy at low and high frequencies.

Table 4: ECM parameters obtained by fitting the EIS spectrum of the LIB shown in Figure 12.

Parameter	Numerical Value
R_{∞}	$0.11 \, \Omega$
$R_{\text{ct},1}$	$1.69 \times 10^{-2} \, \Omega$
$R_{\text{ct},2}$	$2.12 \times 10^{-2} \, \Omega$
$R_{\text{ct},3}$	$5.23 \times 10^{-2} \, \Omega$
τ_1	$2.34 \times 10^{-3} \, \text{s}$
τ_2	$0.20 \, \text{s}$
τ_3	$75.30 \, \text{s}$
ϕ_1	0.54
ϕ_2	0.94
ϕ_3	0.79
L_0	$7.61 \times 10^{-7} \, \text{H}$

4. Perspective and Future Work

We have shown that the DRT can be interpreted as a GP. In essence, GPs generalize Gaussian RVs and the GP-DRT extends the Bayesian DRT methods previously developed by our group [49, 57, 73]. In the GP-DRT, we first define the latent (or unseen) function $\gamma(\xi)$, which we identify as the DRT, to be a GP. We recall that $\xi = \log f = -\log \tau$ and that $\gamma(\xi)$ is indicated interchangeably as $\gamma(\log \tau)$, or $\gamma(\log f)$, and a similar notational abuse is used for $Z_{\text{im}}^{\text{DRT}}(f)$ and $Z_{\text{im}}^{\text{DRT}}(\xi)$. Then, we apply a linear functional to $\gamma(\xi)$ to obtain $Z_{\text{im}}^{\text{DRT}}(\xi)$, the imaginary part of the impedance. In doing that, we show that $\gamma(\xi)$ and $Z_{\text{im}}^{\text{DRT}}(\xi)$ are two correlated GPs. The GP-DRT consistently manages to identify the hyperparameters without sacrificing computational tractability. The GP-DRT can be used to solve two major challenges: 1) the inverse problem of determining the DRT given the impedance data; and 2) the prediction of the impedance together with its credibility. It is important to note that one of the most striking features of GP-DRT is that it overcomes the limitations of all approaches used to date for the analysis of the DRT. This is because it allows us to select the hyperparameters rationally by maximizing the experimental evidence.

Despite being highly effective, the GP-DRT has a few shortcomings, which are not addressed in this report. First, as it is currently formulated, the GP-DRT does not allow using the real part of the data. Second, we have not enforced any constraint on the DRT, for example, there are no constraints set for $\gamma(\xi)$ with $\gamma(\xi) \geq 0$. Third, we implement the current GP-DRT only with a squared exponential kernel. Hereon, we will suggest methodologies that can be used to tackle these two issues.

4.1. Including the Real Part of the Data

Equation (35) highlights one major limitation of the current formulation of the GP-DRT: using the real part of the impedance data leads to infinite entries in the covariance matrix. Such an inconsistency can be overcome if

bounds of integration are changed in the functionals. For example, the following can be defined:

$$\mathcal{L}_{\xi}^{\text{re}}(\cdot) = \int_{\xi_{\min}}^{\xi_{\max}} \frac{1}{1 + \left(2\pi e^{\xi - \hat{\xi}}\right)^2}(\cdot) \, d\hat{\xi} \quad (54a)$$

$$\mathcal{L}_{\xi}^{\text{im}}(\cdot) = - \int_{\xi_{\min}}^{\xi_{\max}} \frac{2\pi e^{\xi - \hat{\xi}}}{1 + \left(2\pi e^{\xi - \hat{\xi}}\right)^2}(\cdot) \, d\hat{\xi} \quad (54b)$$

4.2. Positivity Constraint

As seen in the many examples above, the latent $\gamma(\xi)$ estimated using the GP-DRT model often oscillates away from the peak, especially at the rim of the frequency spectrum. Also, the GP-DRT model repeatedly leads to estimated $\gamma(\xi)$'s that are not positive everywhere, where negative values of $\gamma(\xi)$ are unphysical. Such a limitation can be overcome by constraining the latent variable $\gamma(\xi)$ to be positive. Inspired by works on classification [67, 78], this constraint can be implemented by modifying the joint posterior to include a probit likelihood prior that enforces $\gamma(\xi) \geq 0$ [79]. Algorithmically, this is done by approximating the corresponding probability density functions (PDFs) either with a Laplace approximation or an expectation propagation algorithm [80, 81].

4.3. Choosing the Kernel

In this work, we constrained the kernel, see Section 2.3.4, to be a single squared exponential with a length scale parameter ℓ . However, this is not the only choice; different kernels or combination of kernels could have been used [67]. In principle, instead of defining the kernels in advance, the structures of kernels could have been inferred from the data [82] for example by leveraging the Kramers-Kronig relationships [50] and their connection to the Hilbert transform [83]. Also, the selection of kernel functions and parameter estimation can also be implemented by the combination of GPs and the approximate Bayesian computation algorithm [84].

5. Conclusions

In this work, we have developed the GP-DRT model. The GP-DRT is a novel theoretical framework based on GP that recovers the DRT from EIS data using analytical expressions without the need for choosing the model hyperparameters arbitrarily. The model assumes that the DRT, $\gamma(\xi)$, is a GP. Using the definition of DRT and its relationship to the impedance, it follows that the imaginary part of the impedance, $Z_{\text{im}}^{\text{DRT}}(f)$, is also a GP. Therefore, the PDFs of $\gamma(\xi)$ and $Z_{\text{im}}^{\text{DRT}}(f)$ can be obtained by conditioning with respect to the experimental data. While the performance of the GP-DRT model is strongly affected by its hyperparameters, they can be chosen rationally by maximizing the experimental evidence (*i.e.*, minimizing the NLLM $L(\boldsymbol{\theta})$). Both synthetic experiments and real experiments indicate that the GP-DRT framework is capable of recovering both the latent DRT and the impedance, even for measurements with a high noise level, overlapping timescales, or incomplete (spectrally truncated) data. In

reference to the latter issues, the GP-DRT can predict the impedance values and their uncertainty at unmeasured frequencies. Moreover, the GP-DRT model can include the inductances without deteriorating its performance.

We also observe that the GP-DRT model performs well when “real” experiments are analyzed. The method is particularly well suited to fit the imaginary part of the impedance data. This feature is attributed to the strategy used to optimize the hyperparameters. These hyperparameters are obtained by maximizing the likelihood of the experimental data.

In summary, the GP-DRT model proposed in this article provides a completely new approach to DRT analysis. Not only can the credibility of the obtained results be assessed, but also the model hyperparameters can be chosen rationally. This approach will certainly stimulate further work and improvement in this area.

Appendix A Multivariate Gaussian Random Variables

We recall that a multivariate Gaussian RV \mathbf{z} with mean $\boldsymbol{\mu}$ and a positive definite covariance matrix $\boldsymbol{\Sigma} \succ 0$ is defined as $\mathbf{z} \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ and its probability distribution function is

$$\begin{aligned} p(\mathbf{z}) &= \mathcal{N}(\mathbf{z}|\boldsymbol{\mu}, \boldsymbol{\Sigma}) \\ &= ((2\pi)^N \det(\boldsymbol{\Sigma}))^{-\frac{1}{2}} \exp\left(-\frac{1}{2}(\mathbf{z} - \boldsymbol{\mu})^\top \boldsymbol{\Sigma}^{-1}(\mathbf{z} - \boldsymbol{\mu})\right) \end{aligned} \quad (55)$$

650 For notational convenience, we can partition the Gaussian RV as follows:

$$\mathbf{z} = \begin{pmatrix} \mathbf{x} \\ \mathbf{y} \end{pmatrix} \quad (56)$$

where the corresponding means and covariances are

$$\boldsymbol{\mu} = \begin{pmatrix} \boldsymbol{\mu}_x \\ \boldsymbol{\mu}_y \end{pmatrix} \quad (57a)$$

$$\boldsymbol{\Sigma} = \begin{pmatrix} \boldsymbol{\Sigma}_{xx} & \boldsymbol{\Sigma}_{xy} \\ \boldsymbol{\Sigma}_{xy}^\top & \boldsymbol{\Sigma}_{yy} \end{pmatrix} \quad (57b)$$

Below, we apply marginalization and conditioning and write the PDF of \mathbf{x} and of $\mathbf{x}|\mathbf{y}$, respectively.

A.1 Marginalization

Using (56) and (57), we can obtain the PDF of \mathbf{x} by integrating \mathbf{y} out as

$$\begin{aligned} p(\mathbf{x}) &= \int p(\mathbf{z}|\boldsymbol{\mu}, \boldsymbol{\Sigma}) \, d\mathbf{y} \\ &= \mathcal{N}(\mathbf{x}|\boldsymbol{\mu}_x, \boldsymbol{\Sigma}_{xx}) \end{aligned} \quad (58)$$

or equivalently we can write

$$\mathbf{x} \sim \mathcal{N}(\boldsymbol{\mu}_x, \boldsymbol{\Sigma}_{xx}) \quad (59)$$

655 A.2 Conditioning

The probability of \mathbf{x} known \mathbf{y} is defined as follows:

$$\begin{aligned} p(\mathbf{x}|\mathbf{y}) &= \frac{p(\mathbf{x}, \mathbf{y})}{p(\mathbf{y})} \\ &= \mathcal{N}(\mathbf{x}|\boldsymbol{\mu}_{x|y}, \boldsymbol{\Sigma}_{x|y}) \end{aligned} \quad (60)$$

where

$$\boldsymbol{\mu}_{x|y} = \boldsymbol{\mu}_x + \boldsymbol{\Sigma}_{xy} \boldsymbol{\Sigma}_{yy}^{-1} (\mathbf{y} - \boldsymbol{\mu}_y) \quad (61a)$$

$$\boldsymbol{\Sigma}_{x|y} = \boldsymbol{\Sigma}_{xx} - \boldsymbol{\Sigma}_{xy} \boldsymbol{\Sigma}_{yy}^{-1} \boldsymbol{\Sigma}_{xy}^\top \quad (61b)$$

or equivalently

$$\mathbf{x}|\mathbf{y} \sim \mathcal{N}(\boldsymbol{\mu}_{x|y}, \boldsymbol{\Sigma}_{x|y}) \quad (62)$$

Appendix B Matrices Used in the GP-DRT: Derivations and Properties

B.1 $\mathcal{L}_{\text{im}} \mathbf{K}$ and $\mathcal{L}_{\text{im}}^\# \mathbf{K}$

660 We consider the kernel to be radial, *i.e.*, $k(\xi, \xi') = k(|\xi - \xi'|)$, and recall (15) and (18b)

$$\mathcal{L}_{\xi'}^{\text{im}}(k(\xi, \xi')) = - \int_{-\infty}^{\infty} \frac{2\pi e^{\xi' - \hat{\xi}}}{1 + (2\pi e^{\xi' - \hat{\xi}})^2} k(\xi, \hat{\xi}) \, d\hat{\xi} \quad (63)$$

Specifically, the (18b) can be written explicitly as

$$\begin{aligned} \mathcal{L}_{\text{im}} \mathbf{K}(\xi_n, \xi_m) &= \mathcal{L}_{\xi'}^{\text{im}}(k(\xi, \xi'))|_{\xi_n, \xi_m} \\ &= - \int_{-\infty}^{\infty} \frac{2\pi e^{\xi_m - \hat{\xi}}}{1 + (2\pi e^{\xi_m - \hat{\xi}})^2} k(\xi_n, \hat{\xi}) \, d\hat{\xi} \end{aligned} \quad (64)$$

If we define $\chi = \hat{\xi} - \xi_n$, then we can also write that

$$\mathcal{L}_{\text{im}} \mathbf{K}(\xi_n, \xi_m) = - \int_{-\infty}^{\infty} \frac{2\pi e^{\Delta \xi_{mn} - \chi}}{1 + (2\pi e^{\Delta \xi_{mn} - \chi})^2} k(\chi) \, d\chi \quad (65)$$

where $\Delta \xi_{mn} = \xi_m - \xi_n$. We note that, if the frequencies are logarithmically equispaced (the number of points per decade is set), then $\mathcal{L}_{\text{im}} \mathbf{K}$ is a Toeplitz matrix, a matrix whose descending diagonals are constant. This reduces significantly the computation time as, instead of computing the full N^2 integrals, only $2N - 1$ are needed. We also note that

$$\mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi')) = - \int_{-\infty}^{\infty} \frac{2\pi e^{\xi - \hat{\xi}}}{1 + (2\pi e^{\xi - \hat{\xi}})^2} k(\hat{\xi}, \xi') \, d\hat{\xi} \quad (66)$$

which gives that

$$\begin{aligned} \mathcal{L}_{\text{im}}^\# \mathbf{K}(\xi_n, \xi_m) &= \mathcal{L}_{\xi}^{\text{im}}(k(\xi, \xi'))|_{\xi_n, \xi_m} \\ &= - \int_{-\infty}^{\infty} \frac{2\pi e^{\xi_n - \hat{\xi}}}{1 + (2\pi e^{\xi_n - \hat{\xi}})^2} k(\hat{\xi}, \xi_m) \, d\hat{\xi} \end{aligned} \quad (67)$$

Defining $\chi = \hat{\xi} - \xi_m$ we can write that

$$\mathcal{L}_{\text{im}}^\# \mathbf{K}(\xi_n, \xi_m) = - \int_{-\infty}^{\infty} \frac{2\pi e^{\Delta\xi_{nm} - \chi}}{1 + (2\pi e^{\Delta\xi_{nm} - \chi})^2} k(\chi) \, d\chi \quad (68)$$

It follows that by comparing (65) and (68) that

$$\mathcal{L}_{\text{im}}^\# \mathbf{K}(\xi_n, \xi_m) = \mathcal{L}_{\text{im}} \mathbf{K}(\xi_m, \xi_n) \quad (69)$$

670 and that

$$\mathcal{L}_{\text{im}}^\# \mathbf{K} = \mathcal{L}_{\text{im}} \mathbf{K}^\top \quad (70)$$

B.2 $\mathcal{L}_{\text{im}}^2 \mathbf{K}$

Interestingly, we can transform (18d) from a double integral into a single integral. We first recall (18d)

$$\mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi_n, \xi_m) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{2\pi e^{\xi_n - \xi'}}{1 + (2\pi e^{\xi_n - \xi'})^2} \frac{2\pi e^{\xi_m - \xi''}}{1 + (2\pi e^{\xi_m - \xi''})^2} k(\xi', \xi'') \, d\xi' \, d\xi'' \quad (71)$$

We perform a change of variables by setting $\chi = \xi' - \xi''$ and $\chi' = \xi' + \xi''$. We note that the Jacobian of this transformation is

$$\frac{\partial(\chi, \chi')}{\partial(\xi', \xi'')} = \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \quad (72)$$

675 therefore

$$d\chi \, d\chi' = \det \left(\frac{\partial(\chi, \chi')}{\partial(\xi', \xi'')} \right) d\xi' \, d\xi'' = 2 \, d\xi' \, d\xi'' \quad (73)$$

The (18d) can be rewritten as

$$\mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi_n, \xi_m) = \frac{1}{2} \int_{-\infty}^{\infty} \left(\int_{-\infty}^{\infty} \frac{2\pi e^{\xi_n - \frac{\chi + \chi'}{2}}}{1 + (2\pi e^{\xi_n - \frac{\chi + \chi'}{2}})^2} \frac{2\pi e^{\xi_m - \frac{\chi' - \chi}{2}}}{1 + (2\pi e^{\xi_m - \frac{\chi' - \chi}{2}})^2} d\chi' \right) k(\chi) \, d\chi \quad (74)$$

The inner integral is

$$\begin{aligned} & \int_{-\infty}^{\infty} \frac{(2\pi)^2 e^{\xi_n + \xi_m - \chi'}}{(1 + (2\pi)^2 e^{2\xi_n - (\chi + \chi')}) (1 + (2\pi)^2 e^{2\xi_m - (\chi' - \chi)})} d\chi' \\ &= (\chi + \Delta\xi_{mn}) \operatorname{csch}(\chi + \Delta\xi_{mn}) \end{aligned} \quad (75)$$

where $\operatorname{csch}(z) = \frac{2}{e^z - e^{-z}}$. This procedure allows us to simplify (18d) as:

$$\mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi_n, \xi_m) = \frac{1}{2} \int_{-\infty}^{\infty} (\chi + \Delta\xi_{mn}) \operatorname{csch}(\chi + \Delta\xi_{mn}) k(\chi) \, d\chi \quad (76)$$

Incidentally, we note that $\mathcal{L}_{\text{im}}^2 \mathbf{K}$ is symmetrical, *i.e.*, $\mathcal{L}_{\text{im}}^2 \mathbf{K} = \mathcal{L}_{\text{im}}^2 \mathbf{K}^\top$ or equivalently $(\mathcal{L}_{\text{im}}^2 \mathbf{K})_{nm} = \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi_n, \xi_m) = \mathcal{L}_{\text{im}}^2 \mathbf{K}(\xi_m, \xi_n) = (\mathcal{L}_{\text{im}}^2 \mathbf{K})_{mn}$, because swapping ξ_n and ξ_m in (18d), does not change the integrand. Furthermore, if the frequencies are equispaced logarithmically, then $\mathcal{L}_{\text{im}}^2 \mathbf{K}$ is a Toeplitz matrix.

B.3 $\mathcal{L}_{\text{re}}^2 \mathbf{K}$

We note that the following holds:

$$\begin{aligned} & \mathcal{L}_{\xi'}^{\text{re}} (\mathcal{L}_{\xi}^{\text{re}} (k(\xi, \xi'))) \big|_{\xi_n, \xi_m} \\ &= \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{1}{1 + \left(2\pi e^{\xi_n - \xi'}\right)^2} \frac{1}{1 + \left(2\pi e^{\xi_m - \xi''}\right)^2} k(\xi', \xi'') \, d\xi' \, d\xi'' \\ &= \infty \end{aligned} \tag{77}$$

as the integrand does not tend to zero if $\xi', \xi'' \rightarrow \infty$

685 Appendix C Gradient of marginal log-likelihood (MLL)

In order to compute the minimum of $L(\boldsymbol{\theta})$, we use gradients and note that [67]

$$\begin{aligned} \frac{\partial}{\partial \theta_j} L(\boldsymbol{\theta}) &= -\frac{1}{2} \mathbf{Z}_{\text{im}}^{\text{exp}^\top} \mathbf{A}(\boldsymbol{\theta})^{-1} \left(\frac{\partial}{\partial \theta_j} \mathbf{A}(\boldsymbol{\theta}) \right) \mathbf{A}(\boldsymbol{\theta})^{-1} \mathbf{Z}_{\text{im}}^{\text{exp}} + \\ &\quad + \frac{1}{2} \text{tr} \left(\mathbf{A}(\boldsymbol{\theta})^{-1} \left(\frac{\partial}{\partial \theta_j} \mathbf{A}(\boldsymbol{\theta}) \right) \right) \end{aligned} \tag{78}$$

where if $\boldsymbol{\theta} = \left(\sigma_n, \sigma_f, \ell \right)^\top$, then

$$\mathbf{A}(\boldsymbol{\theta}) = \mathcal{L}_{\text{im}}^2 \mathbf{K}(\sigma_f, \ell) + \sigma_n^2 \mathbf{I} \tag{79}$$

or if $\boldsymbol{\theta} = \left(\sigma_n, \sigma_f, \ell, \sigma_L \right)^\top$, then

$$\mathbf{A}(\boldsymbol{\theta}) = \mathcal{L}_{\text{im}}^2 \mathbf{K}(\sigma_f, \ell) + \sigma_n^2 \mathbf{I} + \sigma_L^2 \mathbf{h} \mathbf{h}^\top \tag{80}$$

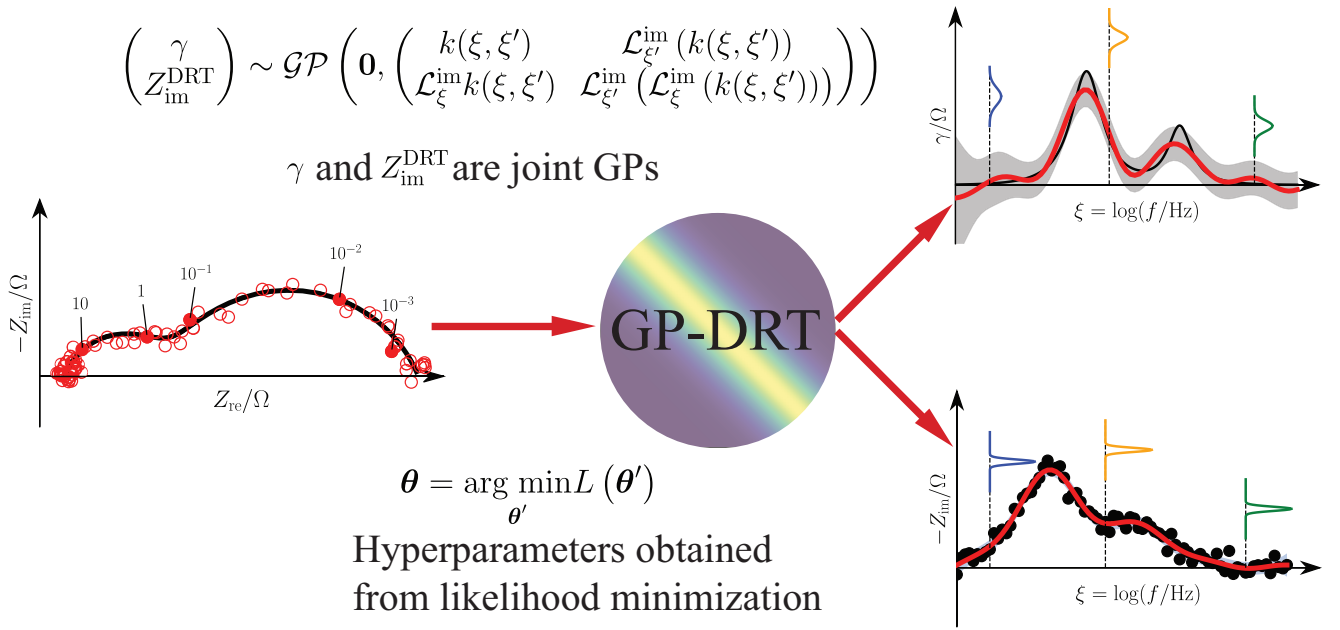

Figure 1: Schematic illustration of the GP-DRT framework.

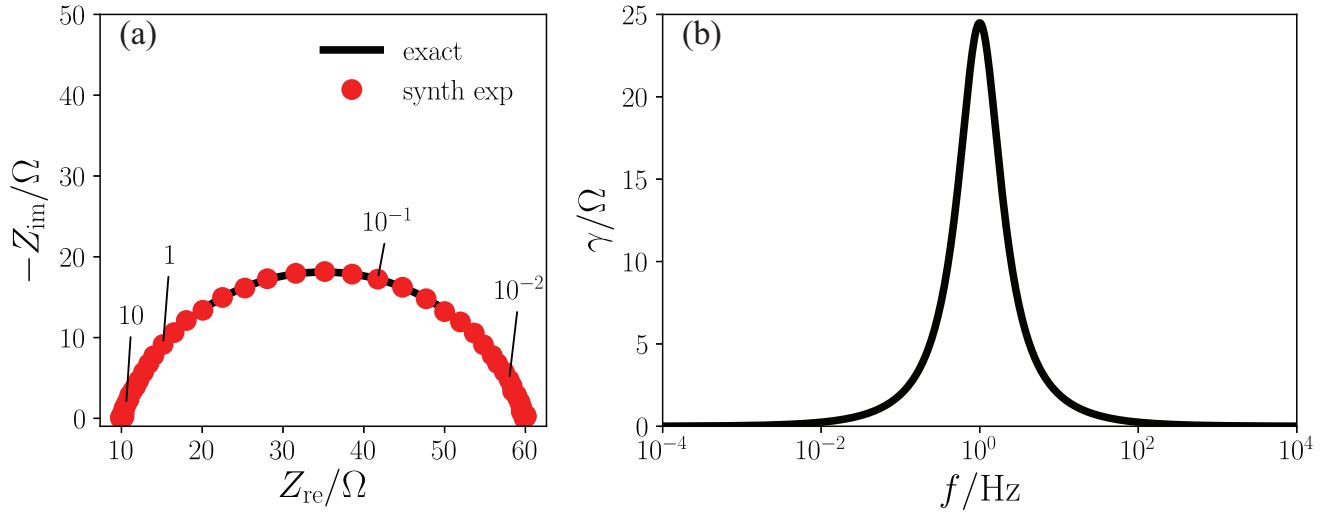

Figure 2: (a) Nyquist plot of the exact ZARC impedance, Z , (solid line) and the synthetic experimental data (red dots) ($\sigma_n^{\text{exp}} = 0.1 \Omega^{1/2}$), and (b) the corresponding exact DRT, γ . Note $\xi = \log f$.

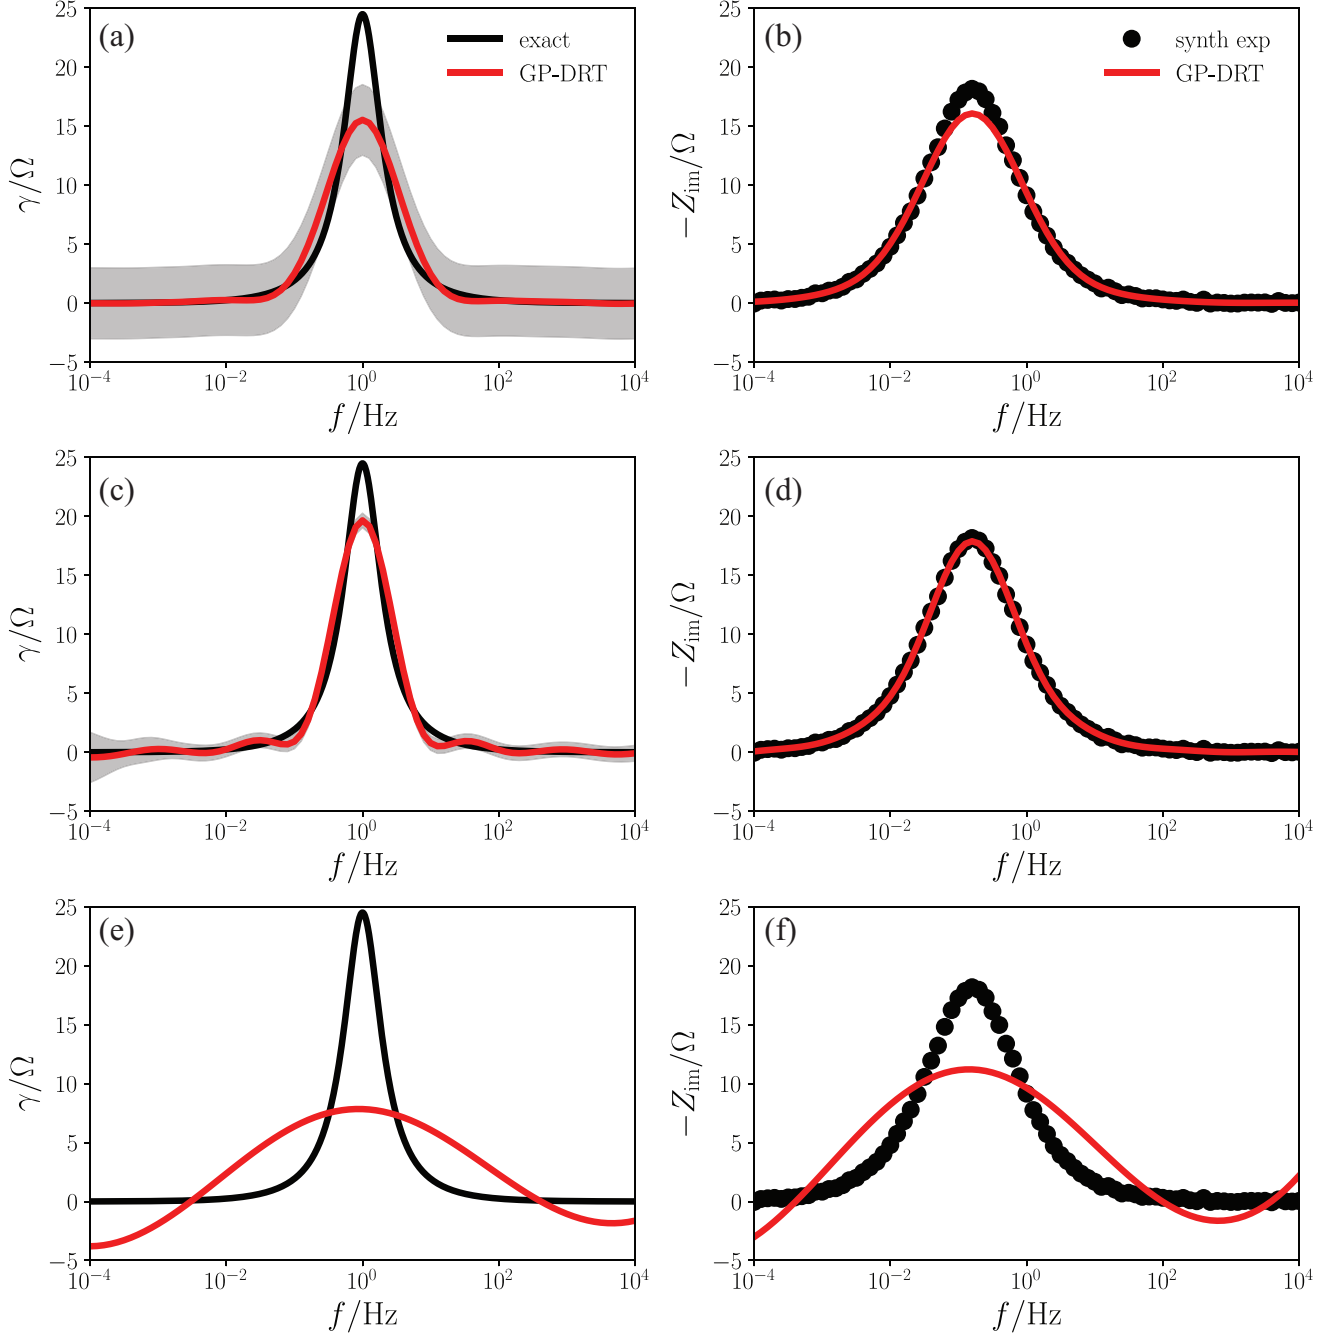

Figure 3: Recovered DRT, γ , (left panels) and imaginary part of the impedance, Z_{im} , (right panels) for different kernel length scales: (a) and (b) $\ell = 10^{-2}$; (c) and (d) $\ell = 1$; and (e) and (f) $\ell = 10$. $\sigma_n = \sigma_n^{\text{exp}} = 0.1 \Omega^{1/2}$ was used for all plots.

Figure 4: Values of the entries of the, (a) and (b), \mathbf{K} and, (b) and (d), $\mathcal{L}^2 \mathbf{K}$ matrices. (a) and (b) correspond to $\ell = 10^{-2}$, while (c) and (d) to $\ell = 1$. The row and column numbers have been substituted by the corresponding frequencies.

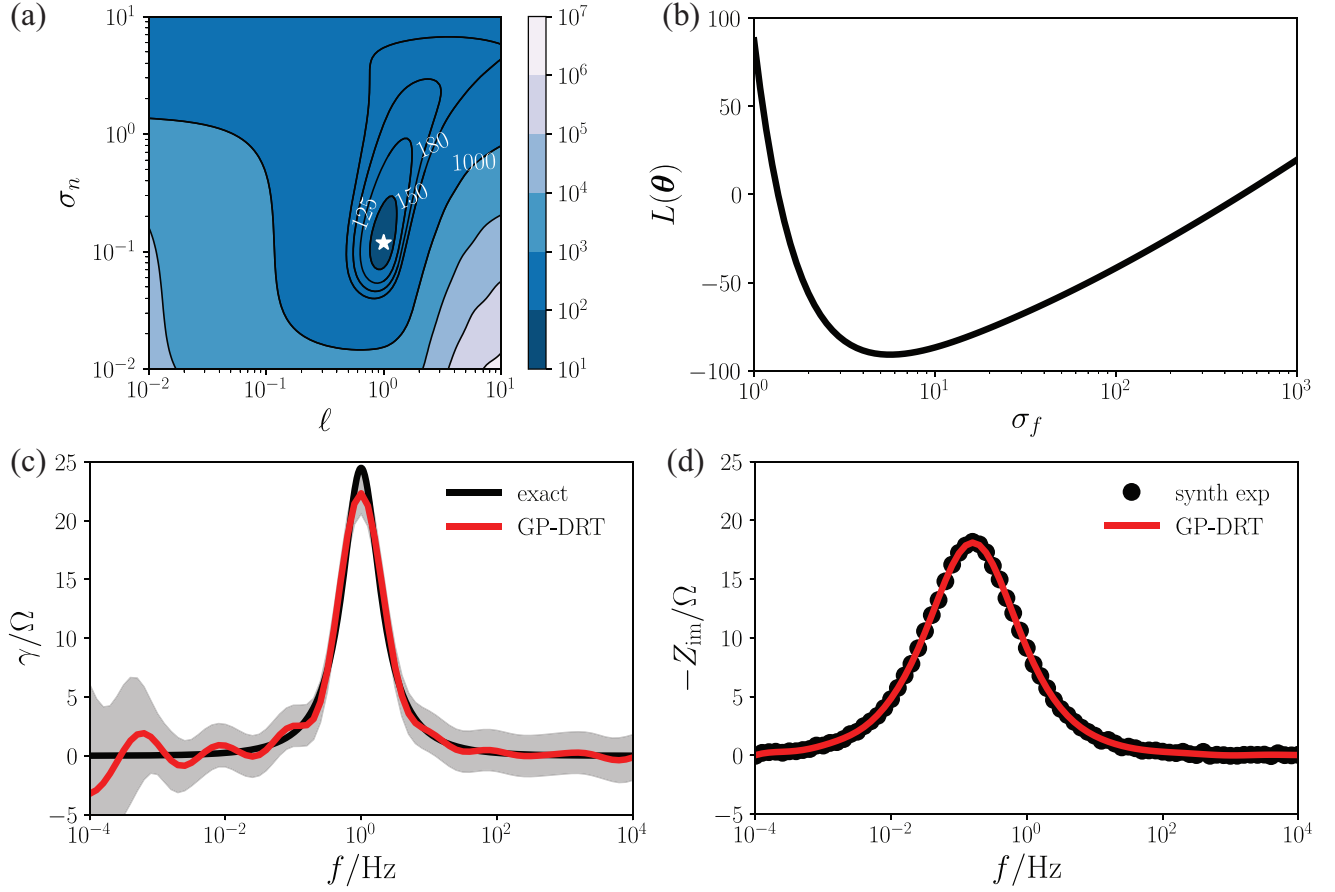

Figure 5: (a) $L(\theta)$ as a function of ℓ and σ_n with $\sigma_f = 1$; (b) $L(\theta)$ versus σ_f with ℓ and σ_n at the values at the star symbol in panel (a). The recovered (c) DRT, γ , and (d) imaginary part of the impedance, Z_{im} .

Figure 6: Box plot of the optimal hyperparameters (a) σ_n , (b) σ_f , and (c) ℓ obtained by minimizing $L(\theta)$ over 10,000 stochastic experiments, 1,000 for each σ_n^{exp} shown.

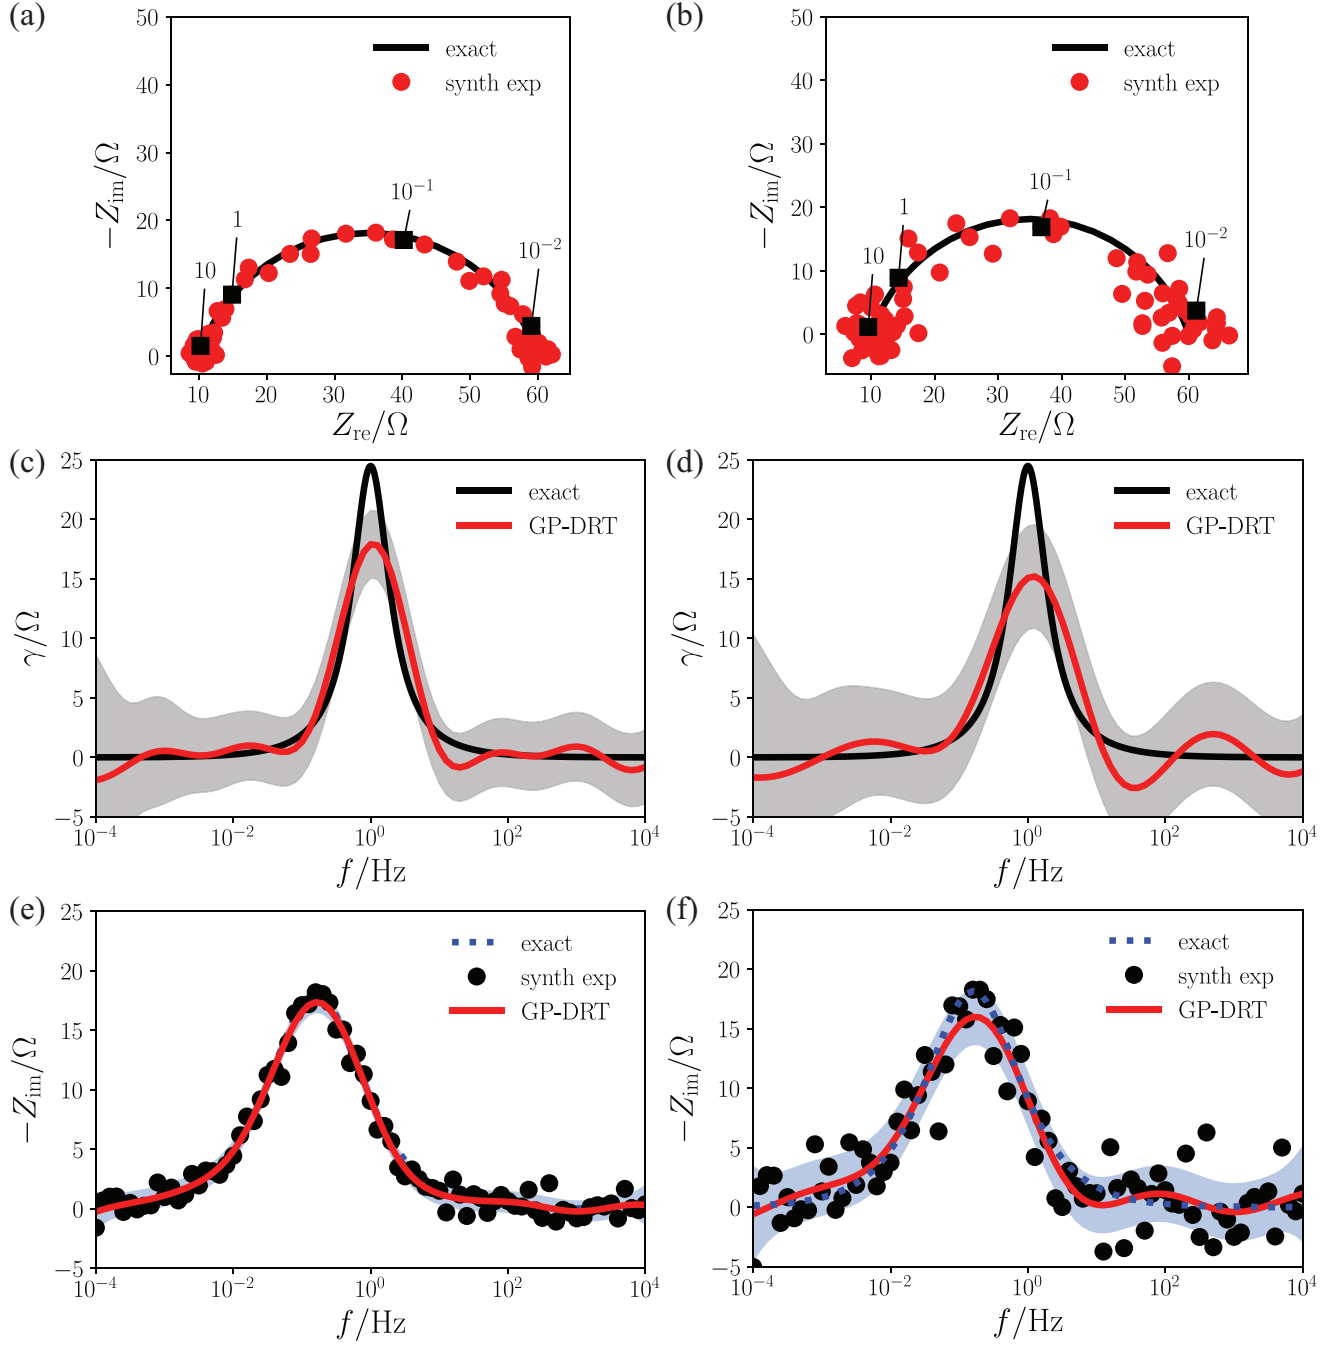

Figure 7: Nyquist plot of synthetic experimental impedance with (a) $\sigma_n^{\text{exp}} = 1.0 \Omega^{1/2}$ and (b) $\sigma_n^{\text{exp}} = 3.0 \Omega^{1/2}$. The recovered $\gamma(\xi)$, (c) and (d), and $Z_{\text{im}}(f)$, (e) and (f), are also shown. (c) and (e) correspond to $\sigma_n^{\text{exp}} = 1.0 \Omega^{1/2}$, (panel a). (d) and (f) correspond to $\sigma_n^{\text{exp}} = 3.0 \Omega^{1/2}$ (panel b).

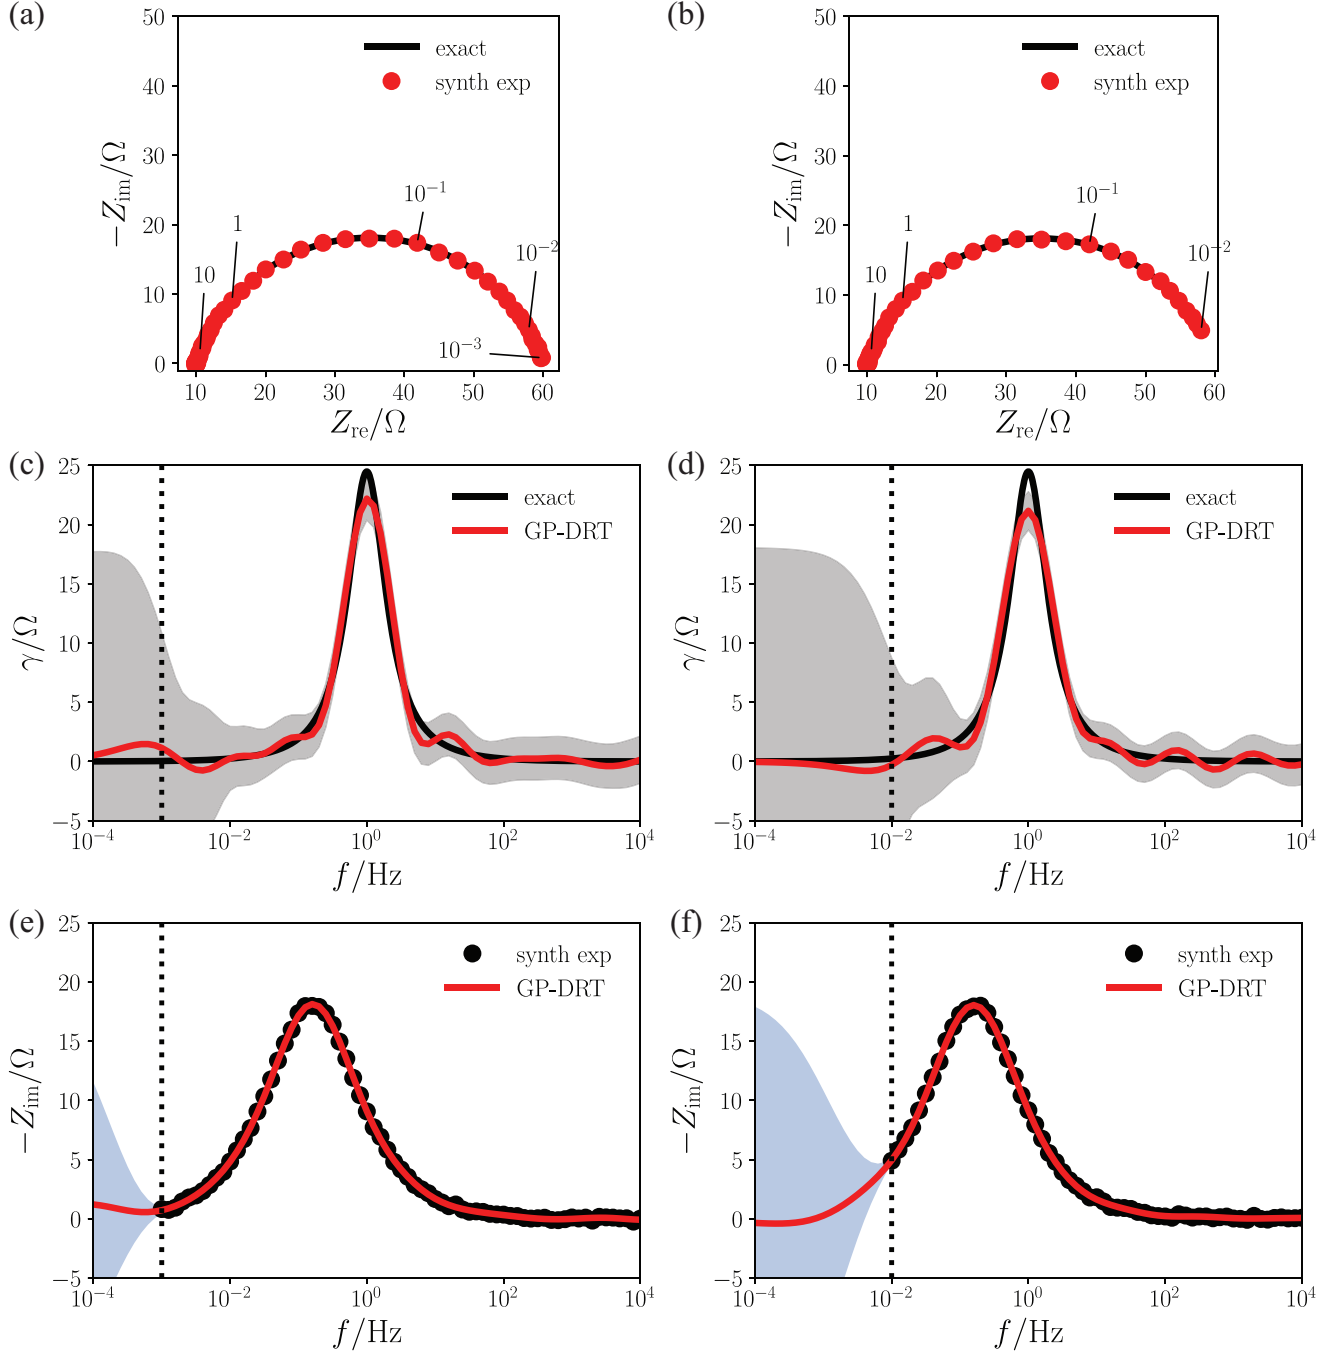

Figure 8: Nyquist plot of synthetic experimental impedance data truncated at (a) 10^{-3} Hz and (b) 10^{-2} Hz; both plots have $\sigma_n^{\text{exp}} = 0.1 \Omega^{1/2}$. The predicted DRT, γ , (c) and (d), and imaginary part of the impedance, Z_{im} , (e) and (f), are also shown.

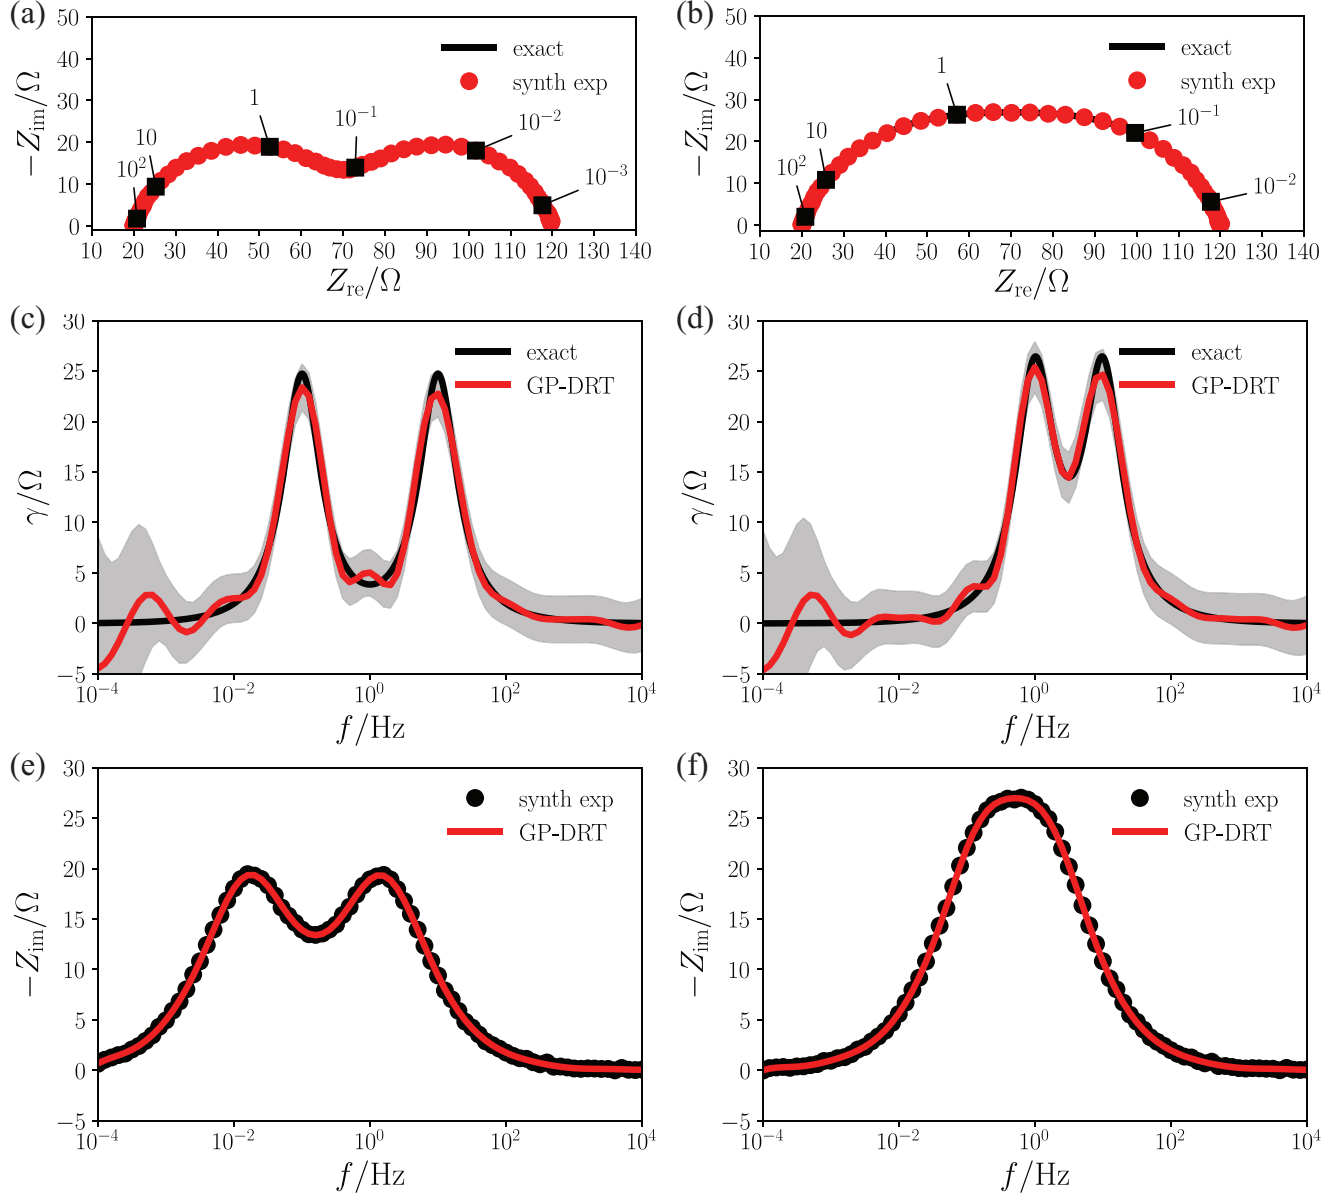

Figure 9: Nyquist plot of the exact impedance (solid line) and synthetic experimental data (red dots) of two ZARCs with (a) $\tau_1 = 0.1$ s and $\tau_2 = 10$ s, and (b) $\tau_1 = 0.1$ s and $\tau_2 = 1.0$ s; both plots have $\sigma_n^{\text{exp}} = 0.1 \Omega^{1/2}$. The recovered DRT, γ , (c) and (d), and imaginary part of the impedance, Z_{im} , (e) and (f) are also illustrated.

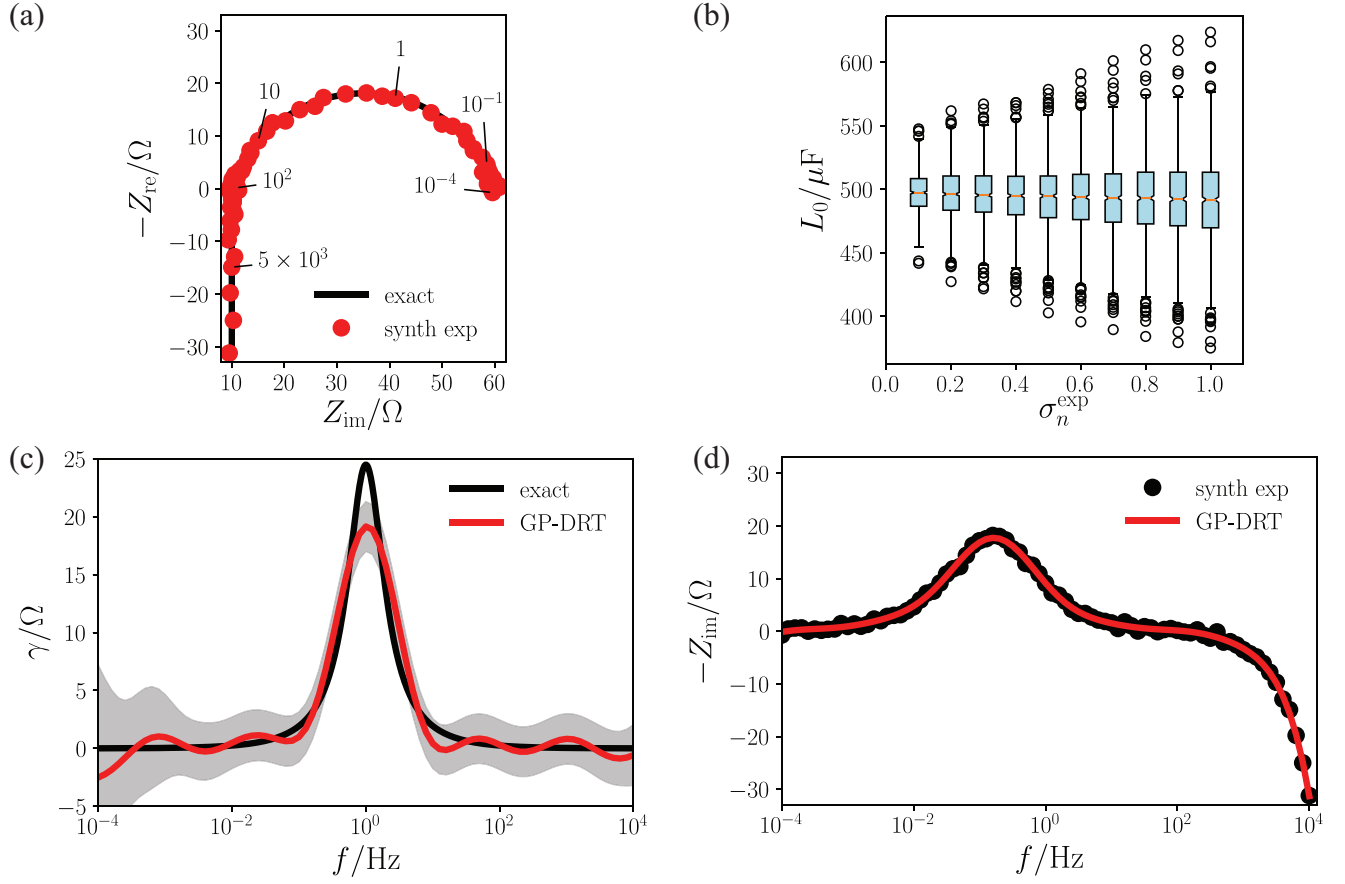

Figure 10: (a) Nyquist plot of a single ZARC element plus an inductance ($\sigma_n^{\text{exp}} = 0.5 \Omega^{1/2}$). (b) Box plot of estimated \bar{L}_0 as a function of σ_n^{exp} . (c) Recovered DRT, γ , and (d) imaginary part of the impedance, Z_{im} .

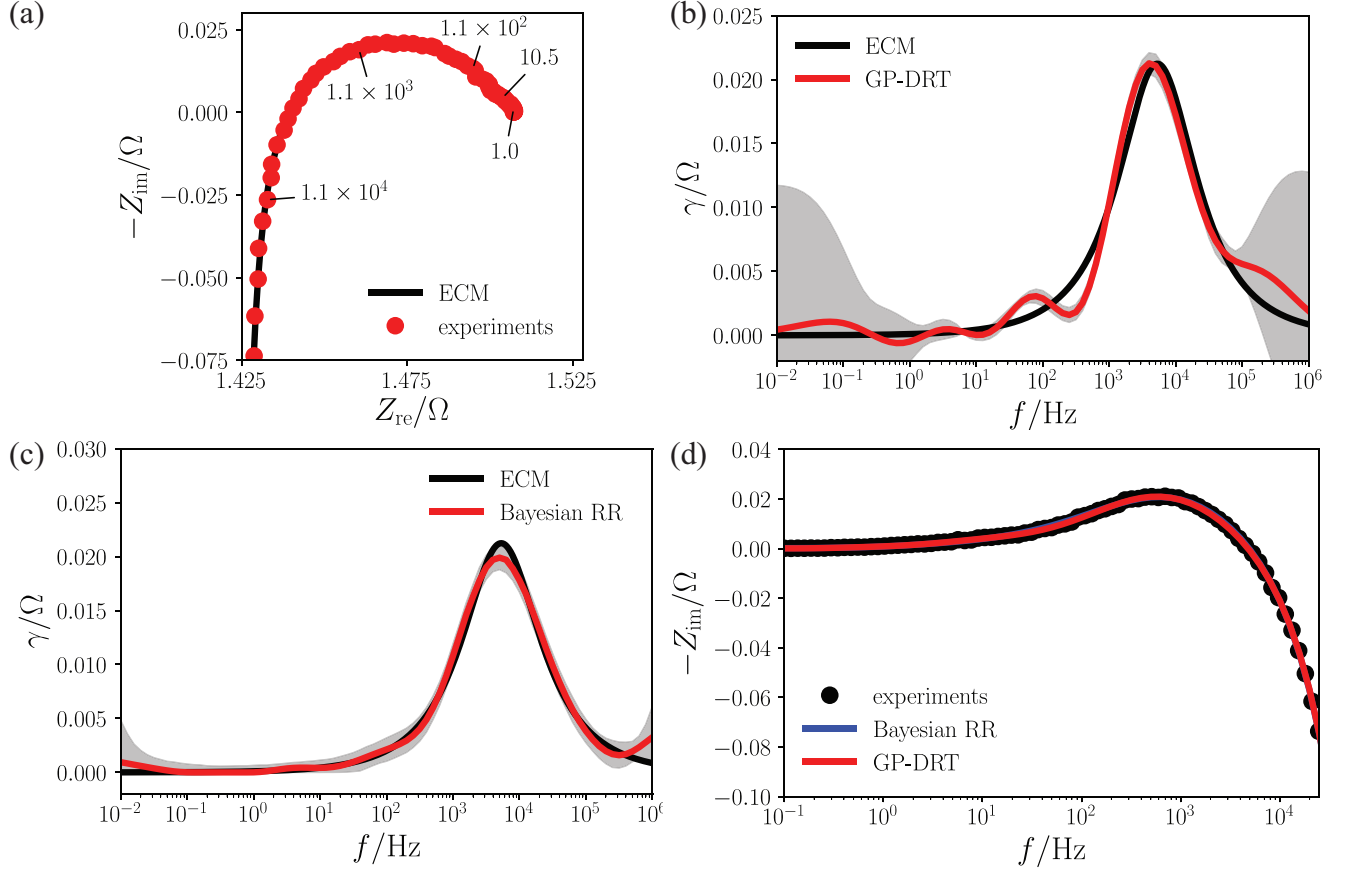

Figure 11: (a) Nyquist plot of the impedance of the experimental SOFC data (red dots) and fitted ECM (solid line). Recovered DRT, γ , by (b) the GP-DRT method and (c) Bayesian RR, where in both panels the DRT of the reference ECM is also shown. (d) The imaginary part of the impedance, Z_{im} , obtained by the GP-DRT (red) and Bayesian RR (blue) and comparison with the experimental EIS.

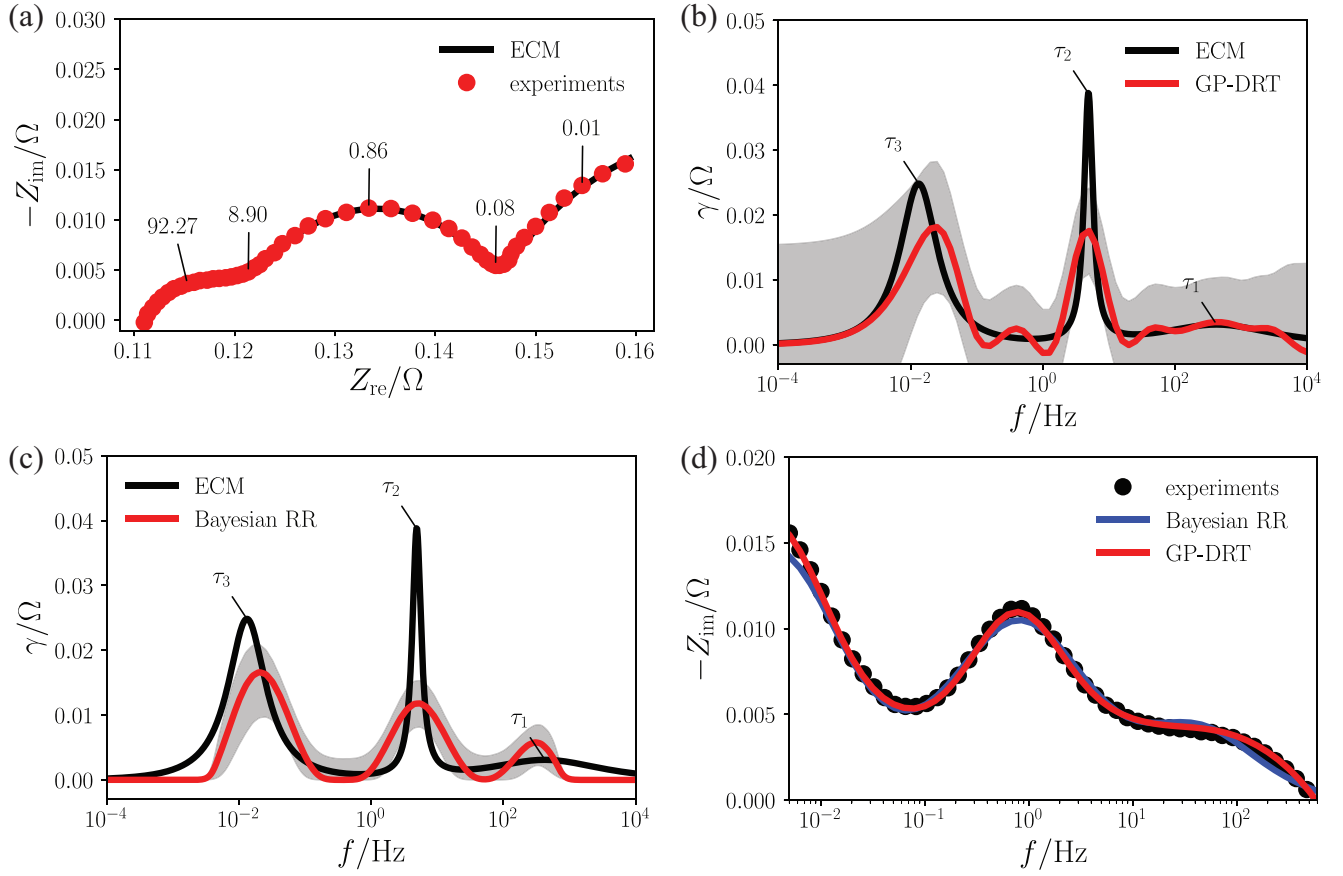

Figure 12: (a) Nyquist plot of the EIS response of a commercial LIB (red dots) fitted using an ECM consisting of 3 ZARCs (solid line). Recovered DRT, γ , by (b) the GP-DRT method and (c) Bayesian RR. (d) The recovered imaginary part of the impedance, Z_{im} , by GP-DRT (red) and Bayesian RR (blue) compared with the experimental data.
